# SHORT CONTENTS

# OXFORD LIBRARY OF PSYCHOLOGY

The *Oxford Library of Psychology,* a landmark series of handbooks, is published by Oxford University Press, one of the world's oldest and most highly respected publishers, with a tradition of publishing significant books in psychology. The ambitious goal of the *Oxford Library of Psychology* is nothing less than to span a vibrant, wide-ranging field and, in so doing, to fill a clear market need.

Encompassing a comprehensive set of handbooks, organized hierarchically, the *Library* incorporates volumes at different levels, each designed to meet a distinct need. At one level are a set of handbooks designed broadly to survey the major subfields of psychology; at another are numerous handbooks that cover important current focal research and scholarly areas of psychology in depth and detail. Planned as a reflection of the dynamism of psychology, the *Library* will grow and expand as psychology itself develops, thereby highlighting significant new research that will impact on the field. Adding to its accessibility and ease of use, the *Library* will be published in print and, later on, electronically.

The *Library* surveys psychology's principal subfields with a set of handbooks that capture the current status and future prospects of those major subdisciplines. This initial set includes handbooks of social and personality psychology, clinical psychology, counseling psychology, school psychology, educational psychology, industrial and organizational psychology, cognitive psychology, cognitive neuroscience, methods and measurements, history, neuropsychology, personality assessment, developmental psychology, and more. Each handbook undertakes to review one of psychology's major subdisciplines with breadth, comprehensiveness, and exemplary scholarship. In addition to these broadly conceived volumes, the *Library* also includes a large number of handbooks designed to explore in depth more specialized areas of scholarship and research, such as stress, health and coping, anxiety and related disorders, cognitive development, or child and adolescent assessment. In contrast to the broad coverage of the subfield handbooks, each of these latter volumes focuses on an especially productive, more highly focused line of scholarship and research. Whether at the broadest or most specific level, however, all of the *Library* handbooks offer synthetic coverage that reviews and evaluates the relevant past and present research and anticipates research in the future. Each handbook in the *Library* includes introductory and concluding chapters written by its editor to provide a roadmap to the handbook's table of contents and to offer informed anticipations of significant future developments in that field.

An undertaking of this scope calls for handbook editors and chapter authors who are established scholars in the areas about which they write. Many of the nation's and world's most productive and best-respected psychologists have agreed to edit *Library* handbooks or write authoritative chapters in their areas of expertise.

For whom has the *Oxford Library of Psychology* been written? Because of its breadth, depth, and accessibility, the *Library* serves a diverse audience, including graduate students in psychology and their faculty mentors, scholars, researchers, and practitioners in psychology and related fields. Each will find in the *Library* the information he or she seeks on the subfield or focal area of psychology in which they work or are interested.

Befitting its commitment to accessibility, each handbook includes a comprehensive index, as well as extensive references to help guide research. And because the *Library* was designed from its inception as an online as well as a print resource, its structure and contents will be readily and rationally searchable online. Further, once the *Library* is released online, the handbooks will be regularly and thoroughly updated.

In summary, the *Oxford Library of Psychology* will grow organically to provide a thoroughly informed perspective on the field of psychology, one that reflects both psychology's dynamism and its increasing interdisciplinarity. Once published electronically, the *Library* is also destined to become a uniquely valuable interactive tool, with extended search and browsing capabilities. As you begin to consult this handbook, we sincerely hope you will share our enthusiasm for the more than 500-year tradition of Oxford University Press for excellence, innovation, and quality, as exemplified by the *Oxford Library of Psychology.*

**David H. Barlow**

David H. Barlow received his Ph.D. from the University of Vermont in 1969. He is a Professor of Psychology and Psychiatry at Boston University, where he founded the Center for Anxiety and Related Disorders and now serves as the Center's Director Emeritus.

Dr. Barlow is the recipient of the 2000 American Psychological Association (APA) Distinguished Scientific Award for the Applications of Psychology. He is also the recipient of the 2008 Career/Lifetime Achievement Award from the Association for Behavioral and Cognitive Therapies and the 2000 Distinguished Scientific Contribution Award from the Society of Clinical Psychology of the APA.

He is past-president of the Society of Clinical Psychology of the APA and the Association for Behavioral and Cognitive Therapies, past-editor of several journals, and currently Editor-in-Chief of the *Treatments That Work* series for Oxford University Press. He was Chair of the American Psychological Association Task Force of Psychological Intervention Guidelines, and was a member of the DSM-IV Task Force of the American Psychiatric Association. He is also a diplomat in clinical psychology for the American Board of Professional Psychology and maintains a private practice.

# Overview and Introduction

# A Prolegomenon to Clinical Psychology: Two 40-year Odysseys

David H. Barlow

**Abstract**

In 1969, David Shakow, generally acknowledged as the founding father of modern-day clinical psychology, recounted his 40-year odyssey in the field. He focused on advances in training, diagnosis and assessment, and treatment, and projected trends in these areas in the years to come. The author recounts his own 40-year odyssey, beginning in 1969, and reflects on the remarkable growth of clinical psychology, progress that has occurred in the areas of training, diagnosis and assessment, and treatment, and the extent to which Shakow's vision has been realized.

**Key Words:** Assessment, clinical psychology, diagnosis, psychological treatment, training

In 1969, two events occurred that would ultimately impact this handbook of clinical psychology. First, my career officially commenced with the conferral of a PhD. For me, this was the fulfillment of a dream that had begun in high school when I decided there was nothing else I wanted to be but a clinical psychologist. But a far more significant event caught the attention of most clinical psychologists. David Shakow, widely acclaimed as the father of modern clinical psychology, published a book of his collected papers entitled "Clinical Psychology as Science and Profession: A 40-Year Odyssey" (Shakow, 1969). At the time, Shakow had recently retired as the first chief of the Laboratory of Psychology in the Intramural Research Program of the National Institute of Mental Health (NIMH). Prior to that, his career included stints in both departments of psychiatry and psychology in major universities, as well as key leadership positions in prominent clinical settings, including McLean Hospital in Boston and Worcester State Hospital. Although he had officially retired in 1966, he continued going to work every day, where he would write and supervise research until he died suddenly one morning in his office, in 1981, at the age of 80 (Garmezy & Holzman, 1984).

Shakow is one of only two individuals to be honored by the American Psychological Association (APA) over the course of its history with two of its most prestigious awards: the Distinguished Scientific Contribution Award and the Distinguished Professional Contribution Award. Although he made enormous contributions to our research effort, much of it in the area of schizophrenia, it was Shakow's conceptualization of the role of modern-day clinical psychology that remains his most enduring legacy. He was an early president of the Division (now the Society) of Clinical Psychology of the APA and chaired the very influential Committee on Training in Clinical Psychology that made its report in 1947 defining the Scientist-Practitioner Model of training, a model that was endorsed, broadened, and deepened at the iconic Boulder Conference in 1949 (Raimy, 1950).

It is a coincidence that, as I write this prolegomenon in the summer of 2009, it has been another 40 years since the publication of Shakow's book in 1969, the year my career also commenced, and the field has expanded exponentially. Thus, it seems fitting to reflect on his views and his predictions for the future of the profession as put forth at the end

of his 40-year odyssey and, with all humility, recount my own 40-year odyssey reviewing the major themes articulated by Shakow in 1969, and later elaborated in a major paper in 1976 (Shakow, 1976). These themes include training, diagnosis (by which he meant the broad area of psychological assessment), and therapy. I begin with a look at training.

## Training in 1969

In 1969, Shakow observed:

> Present doctoral training . . . calls for a minimum program of four years, one year of which (preferably the third) consists of an internship. On a foundation of basic courses in theoretical clinical and dynamic psychology, practica, clerkships, and internships are organized. The type of training program now generally accepted was initially proposed by the Committee on Training in Clinical Psychology of the APA in its 1947 report, and, in its major outlines, further supported in conferences at Boulder (Raimy, 1950), Stanford (Strother, 1956) and Miami (Roe, Gustad, Moore, Ross, & Skodak, 1959). (A fourth conference was held in the spring of 1965.) The 1947 Report called for centering clinical training in existing university departments, and the integration of field training units and university programs. (*Shakow*, 1969, p. 39)

Shakow also recounted what he called the "phenomenal" growth in clinical psychology in the United States. As he noted:

> (1) membership in the Division of Clinical Psychology of the APA has risen from 787 in 1948 to 2,883 in 1964; (2) the number of schools fully approved by the Committee on Training in Clinical Psychology of the APA has increased from 30 in 1948 to 55 in 1963; (3) there were an estimated 742 graduate students enrolled in doctoral training in programs in clinical psychology in the academic year 1947–48 compared to 3,340 in 1962–63; (4) the number of clinical psychologists certified by the American Board of Examiners in Professional Psychology has increased from 234 in 1948 to 1,793 in 1963 (of the total, 1,116 are "grandfathers"); (5) 28 states, and four provinces in Canada have established some form of statutory control; 18 states have set up non-statutory control. (*Shakow*, 1969, p. 41)

But he noted that this "unusual growth" had not come about without much travail, and that this growth had given rise to a number of questions that would have to be answered forthrightly in the years to come. Some of these questions were:

1. Can psychology train persons with both professional and scientific goals in mind?

2. How much application can there be in a field where basic knowledge is still so meager?

3. Should not clinical psychologists be devoting more time to research?

4. Should training for research and teaching be separated from training for the applications of psychology? (Shakow, 1969, p. 41)

These questions, of course, reflected the continuing endorsement of the scientist-practitioner model of training of clinical psychologists as conceptualized by Shakow himself, with its emphasis on integration of science and practice, as articulated in various conferences on training sponsored by the APA, most notably the Boulder Conference mentioned earlier. And it is interesting to note that many of these questions raised in the 1960s still remain today, in 2009. But in fact, this philosophy of training psychologists had much deeper roots. Notably, Lightner Witmer, considered the first "clinical psychologist" by most, wrote "the pure and the applied sciences advance in a single front. What retards the progress of one, retards the progress of the other; what fosters one, fosters the other. But in the final analysis the progress of psychology, as of every other science, will be determined by the value and amount of its contributions to the advancement of the human race" (Witmer, 1907/1996, p. 2491; see also Routh, Chapter 2, this volume).

Despite the long history of this model of training for clinical psychology and the substantial amount of time and effort invested in articulating and implementing this model, the desired outcomes proved elusive. For example, in the report of the Boulder Conference itself it was noted, "too often, however, clinical psychologists have been trained in rigorous thinking about nonclinical subject matter and clinical problems have been dismissed as lacking in 'scientific' respectability. As a result, many clinicians have been unable to bridge the gap between their formal training and scientific thinking on the one hand, and the demands of practice on the other. As time passes and their skills become more satisfying to themselves and to others, the task of thinking systematically and impartially becomes more difficult" (Raimy, 1950, p. 86). Nevertheless, the Boulder Conference, under Shakow's influence and leadership, articulated a number of reasons why

joint training in practice and research continued to be desirable:

1. Avoid narrowness of thinking associated with training in just research or practice and foster cross-fertilization by combined training.

2. Lack of dependable knowledge requires that research be a vital part of psychologists skills.

3. Substantial interest in field and the large number of applicants allows for accepting individuals with interests in both science and practice.

4. Direct involvement with clinical practice would highlight important research issues.

5. Effectively delivered service may generate financial support for the initiation and continuation of research and data collection.

It is interesting to reflect on this rationale for training after 60 years. Of course, few would dispute the necessity to avoid narrowness of thinking and to broaden perspectives on both research and practice. Similarly, Point 2 remains an important consideration despite the enormous advances in our understanding of psychopathology and behavior change over the ensuing last 60 years. Nevertheless, this particular point reflects the fact that even today a partnership between frontline clinicians who are actually objectively assessing the effects of their procedures, and clinical researchers responsible for developing and evaluating a variety of psychological procedures is essential if we are to move forward. There is also little question regarding Point 4, that some familiarity with the subject matter at hand through clinical practice greatly enriches the research effort. For Point 3, we are seeing somewhat less than universal agreement that one individual will have substantial and equal interest in both science and practice, nevertheless, this remains a goal of all scientist-practitioner programs that find their graduates either going on to clinical research careers, careers in practice with a more empirical bent, or perhaps some combination. Finally, Point 5 certainly came true with the advent of federal funding for development of psychological procedures that, in turn, provided financial support for training and research. Given the new strategic vision at the NIMH during the last several years (Insel, 2009), some direct connection to the practice effort is seen as a very important link to continued research funding.

As noted earlier, Shakow was a strong advocate of integrating clinical settings fully into doctoral clinical psychology programs. This arrangement was rare in those early years, since hardly any in-house training clinics existed, and sites for clinical practica were few and far between. And when they could be procured, psychologists were often limited to roles of administering routine psychological testing. Nevertheless, Shakow, in 1976, stipulated again a suggestion he had been making for 20 years. "My suggestion is that the university (or professional school) and the field-center training activities be as completely integrated as possible. Integration does not mean sameness, which results in a loss of vigor that comes with having the same point of view… . The fundamental principal of the plan is that theory and practicum must be constantly associated and tied together, whether in the university or the field station, and that both types of activity—theory and practicum—start with the very beginning of the program. I would suggest as axiomatic: *the greater the degree of integration between theory and practice, and between university and field center, the more effective the program*" (Shakow, 1976, p. 556). On this point, it is clear that Shakow's wisdom has been recognized, as clinical psychology programs increasingly conduct training in captive clinics, often referred to as Psychological Service Centers, and increasingly, specialty clinics focusing on specific areas of psychopathology. Nevertheless, the necessity of completing internships in more fully organized clinical settings, still a requirement of all scientist-practitioner programs, is becoming increasingly problematic. There is a decreasing number of internship slots and at the same time a rapidly increasing number of applicants, resulting in a greater number of students each year unable to complete requirements for the PhD degree due to circumstances largely out of their control or that of their clinical psychology doctoral program. Clearly, this is an untenable situation and requires a new look at the admonitions made by Shakow over 40 years ago, recommending control of the entire clinical psychology training experience by the programs with the authority to conduct that training.

So after 40 years, what did Shakow conclude in 1969 about the future of clinical psychology, particularly in the context of training? First, he determined that it was crucial to train for research "… the content of research needs redefinition so it will encompass the most rigorous laboratory research, systematic naturalistic observation, and a serious attitude of inquiry leading to deliberate efforts to obtain answers to questions which arise during clinical operations" (Shakow, 1969, p. 42). This aspiration

reflected, in part, a longstanding difficulty observed by the early leaders of clinical psychology that required research projects in doctoral training programs were conceptualized far too narrowly. That is, most required research efforts in clinical programs were concerned with only the most basic questions, often studying laboratory animals rather than taking advantage of the rich trove of clinical questions that could be addressed more directly in applied settings. Of course, as mentioned, most clinical psychologists in training in those days had little access to these settings.

Second, Shakow argued that clinical psychology training should occur in institutional and community settings, and that "the function of each of the training agencies and the way to integrate their work need careful spelling out" (Shakow, 1969, p. 42). Once again, as articulated earlier, Shakow was a firm believer in the integration of training directly into the clinical settings.

Third, Shakow proposed increased delineation of important areas for clinical research and practice. Toward fulfilling this goal, he suggested that "This calls for much imaginative thinking. New methods of therapy, new methods of diagnosis, and—particularly, preventive methods of education are becoming increasingly important… . It is clear that the personnel shortages in the area of mental health will be enormous and far from filled by present-day mental health professionals. Much thought and experimentation must go into making use of a much larger pool of persons, for example, younger persons with the ideals and resourcefulness represented in Peace Corps volunteers" (Shakow, 1969, p. 42). In this aspiration, Shakow correctly anticipated the greatly increased knowledge of the origins and course of psychopathology, the variety of new interventions both psychological and pharmacological that have occurred in the past 40 years, and the enormous upsurge in interest on the proper ways to deliver mental health services (Barlow, 2004; McHugh & Barlow, 2010). If anything, it is this latter area that is attracting the most attention as the reform of our healthcare delivery system in the United States gains traction, and as healthcare delivery in the rest of the developed world becomes more organized, efficient, and evidence-based. I return to this theme below.

Fourth, Shakow considered the proper place to locate training programs in clinical psychology. He underscored that the placement of clinical psychology programs in university settings should be carefully considered, so as to achieve his goals of integration in both the theory and application of practice, "The nature of the doctoral degree granted to clinical psychologists—with a strictly professional (say a PsyD) or a combined research degree (the PhD)—calls for special discussion. The place and nature of post-doctoral programs, particularly such programs for psychotherapy training should be given equal thought" (Shakow, 1969, p. 42).

In this era, professional degrees (PsyD) had just been conceptualized and were being initiated in a few university settings. Shakow did not seem to have a particular view on this development as long as they aspired to the same principles he outlined for ideal training in the field.

Finally, Shakow made observations on upgrading the standards for committees that evaluate training programs and the competency of individuals to practice psychology, noting in particular the potentially important role of the American Board of Professional Psychology, as well as state licensing and certification boards. In a prescient summary statement, Shakow concluded:

> The major problems of clinical psychology continue to lie within the parent field, psychology. Clinical psychology, after a long period spent as part of an academic discipline, has been through the early stages of becoming a profession as well. It is going through the natural disturbances and difficulties which attend a growth process of this kind. However, if it selects its students carefully, for personality as well as intellect; if it trains thoroughly, in spirit as well as letter; if it trains broadly, recognizing that narrowly educated specialists are not true clinical psychologists; if it remains flexible about its training and encourages experimentation; if it does not sacrifice remoter goals to the fulfillment of immediate needs; if it maintains its contact with its scientific background, remaining alert to the importance of theory as well as practice; if it keeps modest in the face of the complexity of its problems, rather than becoming pretentious—in short, if it finds good people and gives them good training—these disturbances and difficulties need not be of serious concern. Its future in society and as a profession is then assured.
> (*Shakow*, 1969, p. 43)

In summary, Shakow's odyssey led him to conclude that (1) science and practice should be integrated and related parts of training, but (2) that the focus of science in clinical psychology training should be on clinically relevant themes. (3) These training experiences should be firmly grounded in academic psychology, but should be fully integrated into front-line practice settings, with increased attention

to organized methods for evaluating quality and competence. And (4), the field should be on the forefront of exploring new systems for delivering broad-based psychological services.

### Training in 2009

Earlier in the chapter, Shakow recounted the "phenomenal" growth in clinical psychology, from the years 1948–64, but even he would be stunned by what has happened since then. To update some of the statistics from the early 1960s listed earlier, membership in the Division (Society) of Clinical Psychology (Division 12) has not only increased substantially, but has spawned numerous additional divisions within the APA. These include, but are not limited to, the Division of Psychotherapy (Division 29), the Society of Clinical Child & Adolescent Psychology (Division 52), and the Society of Pediatric Psychology (Division 53). In addition, many other divisions that exist today would have been subsumed under the Division of Clinical Psychology, such as Divisions 38 (Health Psychology), 39 (Psychoanalysis), 42 (Independent Practice), 40 (Clinical Neuropsychology), 49 (Group Psychology & Group Psychotherapy), and several others. The number of schools fully accredited by APA to offer doctoral-level training has grown from 55 in 1963, to 226 in the 2006 academic year (Grus, this volume). From 3,340 graduate students enrolled in doctoral training programs in clinical psychology in 1962–63, the number has jumped to 25,973 as of 2006 (Grus, this volume). In addition, the number of psychologists certified in clinical psychology by the American Board of Professional Psychology has increased from 1,793 in 1963 to 3,348 as of 2009. And, whereas clinical psychology was the only area in which certification was possible from this board in the early '60s, there are now 13 specialties (see Table 1.1).

Finally, psychologists are under some form of statutory control in every state and province in North America, up from approximately half of the states and provinces in the 1960s. Much more revealing data on the current status of clinical psychology, along with facts on training and credentialing of clinical psychologists, are available in Chapter 8.

Returning to Shakow's vision for the future of clinical psychology, particularly in the context of training, we can now evaluate his predictions in the ensuing 40-year period. One remarkable observation we can make is how little has changed in both underlying philosophy and the implementation of his vision for training. This is best exemplified by

the recent adoption of evidence-based practice (EBP) as policy by the APA (2006). Evidence-based practice has been defined by the APA as "the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (2006). This relatively broad definition of science and practice is perfectly in keeping with the spirit of Shakow's vision that we can now safely say has been realized. In addition, the model he espoused, the Scientist-Practitioner model, is still the most highly valued model for training in the field, despite the appearance of alternative and, in some cases seemingly competing models, as described later. His other recommendations for a greater focus of research on clinical issues, integrating the academy and the clinic, developing new and imaginative ways to deliver services, the location of training programs, and strengthening standards for evaluating competency have all come to pass or are in the process of being realized. We will describe each briefly in turn.

### *Integrating Science and Practice*

It is remarkable how well the fundamental principles of the Scientist-Practitioner model have stood the test of time. As Grus (this volume) points out, from the vantage point of the APA, the three core training models that guide clinical psychology education and training programs "…all emphasize the role of science as it relates to practice." These models

of training include, of course, the Scientist-Practitioner model, with its origins in the late 1940s and still employed by the majority of doctoral programs in clinical psychology today. The Practitioner-Scholar model was formulated at a conference held in Vail, Colorado, in 1973 (Korman, 1976), with the goal of placing greater emphasis on preparation for psychological practice that would, nevertheless, be informed by science. Finally, the Clinical Scientist model, as initially described by McFall (1991), emphasized, as implied in the title, the training of clinical psychologists to be primarily scientists, with a strong focus on mastering principles of the scientific method, discovery of new knowledge, and the critical thinking skills that go along with the process of science. Programs identifying with this model often discourage applicants who are interested, at least exclusively, in clinical practice.

Although a common emphasis on science might seem a stretch for some models, such as the Scholar-Practitioner model, the flexibility in the Scientist-Practitioner model in regard to strategies for integrating science and practice makes this focus very much a part of the type of training offered in at least the leading professional schools. Thus, mental health practitioners may function as scientist-practitioners in one or more of three ways (Barlow, Hayes, & Nelson, 1984; Hayes, Barlow, & Nelson-Gray, 1999). First, they may be consumers of science, in that they keep up with the latest scientific developments in their field and make use of the most current assessment and treatment procedures that would presently be referred to as "evidence-based." A firm foundation in the scientific aspects of clinical psychology would be necessary to evaluate the literature and keep abreast of these developments. Second, the same practitioners, as part of a responsible practice, may evaluate their own assessments or treatment procedures to assess effectiveness in a process now described as "outcomes assessment." In this way, they are accountable not only to their own patients, but also to third parties who may be paying for the services. This evaluative activity has also been encoded recently in principles of EBP, adopted by the APA (2006). Third, scientist-practitioners may conduct research in clinics, hospitals, or elsewhere for the purpose of creating new knowledge about treatments, assessment, or the nature of psychopathology. Much of this new knowledge would then find its way into the clinical psychology literature, where empirical reports are published. Thus, under the influence of EBP (discussed further later), at least two of these three distinct ways in which one could function as a scientist-practitioner are endorsed by leading proponents of all models of training present today in clinical psychology (Barlow et al., 1984; Hayes et al., 1999).

Other evidence on the robustness of this model comes from data collected by Norcross, Karpiak, and Santoro (2005), who conducted one of the periodic surveys of members of the Society of Clinical Psychology that began in the 1960s. Their survey, conducted in late 2003, examined, among other things, the training models followed in clinical psychology graduate programs (restricted in this case to the Scientist-Practitioner or "Boulder" model or the Scholar-Professional or "Vail" model, since the Clinical Scientist model is still relatively new). These models were described rather narrowly, such that the Vail model was represented as focused largely on practice. The data are presented in Table 1.2 (Norcross et al., 2005).

From Table 1.2, one can see that, in 2003, the percentage of Division 12 psychologists hailing from Scientist-Practitioner model programs was slightly over 80%, a number that has remained steady since the 1980s. Looking at the bottom (total percent) row, 65% would prefer the "Boulder" or "Strongly Boulder" model of training if they were "doing over" their training, whereas only 4% would prefer training in a "Vail" or "Strongly Vail" model. In another statistic, only eight of the 463 clinical psychologists trained in Boulder model programs reported that they would prefer a Vail model program if they could do it over again, whereas half of the psychologists trained in the Vail model programs would remain firmly within the Vail model. This is all the more surprising since, as pointed out in Chapter 8, as of 2005, only 40% of the doctorates in clinical psychology earned a PhD, and 53% earned a professional degree, the PsyD. The answer to this discrepancy lies, to some extent, in the conclusion noted earlier, that all training programs these days, under the influence of EBP, are to some degree scientist-practitioner orientated, whether they award the PhD or the PsyD.

### Research Focused on Clinically Relevant Themes in Integrated Practice Settings

Shakow's multifaceted vision is also clearly evident in the current focus of research training that exists in programs in clinical psychology. In the last 40 years, the focus of research, even for required dissertations, has shifted from the basic, nonapplied arena, to a very clear emphasis on clinical research. To accommodate the research productivity within clinical

**Table 1.2  Model Trained in by Model Preference**

| Model trained in | Total % | Model preference (%) | | | | |
|---|---|---|---|---|---|---|
| | | SB | B | E | V | SV |

programs, including students and faculty, the number of journals publishing applied clinical research has proliferated over the past 40 years, beyond the imagination of leading psychologists from the 1960s, such as Shakow himself. In 1965, five psychological journals were publishing primarily clinical research (psychopathology and intervention). In 2009, most popular citation analyses include 87 journals in the category of clinical psychology. In many cases, this research has taken place in the context of entities set up to promote the integration of clinical work and research, as detailed later. And this kind of effort is taking place in both traditional psychology department–based clinical psychology programs, as well as in many (but certainly not all) of the leading professional schools. To illustrate these trends in part, I will briefly describe the example of one of our own research and training clinics at Boston University, the Center for Anxiety and Related Disorders (CARD), although the choice of this Center for description is based as much on familiarity and convenience as any other factor, since equally vibrant clinical research and training entities exist in other universities around the country.

CARD, originally founded at the State University of New York at Albany, relocated to Boston University in 1996. It is a clinical research and treatment facility, operating fully within the Department of Psychology, whose mission is to advance scientific knowledge on the nature and treatment of anxiety and its disorders, as well as of other emotional disorders as they relate to anxiety, and to disseminate this information widely. To this end, the Center pursues several objectives: it conducts research on the nature and origins of anxiety disorders, and on assessment and treatment outcomes for these disorders; it maintains a fundamental mission to educate and train doctoral students in clinical psychology; and it operates as a full-service clinic for the purpose of assessing and treating anxiety and related disorders from referrals by community health professionals.

To accomplish these goals, the Center admits between 500 and 600 new patients a year to its adult and child programs. "Admission" means that patients must first pass a phone screen to rule out obvious problems that are not the focus of CARD, such as current substance use or psychotic disorders. Individuals deemed appropriate are administered a full diagnostic and assessment battery before being referred either internally to one of the CARD clinics or treatment programs, or possibly to other community resources if the presenting problems are not within CARD's realm of expertise. The Center supports approximately 6,000 visits annually from patients receiving care.

The two fundamental goals of CARD are to support clinical training in its doctoral program and clinical research for both trainees and faculty. To accomplish these goals, it was decided at the outset that CARD must provide the best clinical care available. Most individuals would not attend a clinic if they thought that the clinicians were only interested in research and that they would be "guinea pigs" for this research. Rather, they come to alleviate their suffering and restore their functioning, and CARD has developed a reputation for fulfilling these goals. In fact, approximately 60% of patients admitted to CARD enter directly into usual and standard evidence-based clinical care, much of it provided by doctoral students in clinical psychology, but some

provided by psychiatric residents, post-doctoral staff, and faculty. The remaining 40% of the patients (and this number varies considerably, depending on research projects ongoing) are offered the possibility of entering one or another clinical research protocol, in which interventions are evaluated in return for free treatment. CARD also has a clinic for eating disorders, a virtual reality laboratory, and a small program for sleep disorders. New programs are developed and some are discontinued, depending on resources available and the changing interests of faculty members. CARD supports between 30 and 40 full-time staff, including psychologists, psychiatrists, a nurse, and a number of clinic and research technicians. Some of the faculty associated with CARD are on tenure-track lines at the university, but the majority are supported with income generated by CARD through grants or patient fees. Annual income from patient fees and contracts runs between $500,000 and $700,000 a year, which is all fed back into the program for salaries or other resources.

In fiscal year 2009, CARD was supported by approximately $4.5 million in funds, most of it from the National Institutes of Health (NIH), but with some monies from other sources. Among the NIH monies are National Service Research Awards (NRSA), granted to doctoral students who have successfully competed for these funds. Examples of ongoing NRSA awards for doctoral students include a new innovative "summer camp" treatment for young children, aged 4–8, suffering from severe separation anxiety; a study utilizing functional magnetic resonance imaging (fMRI) technology to examine brain functioning during emotional processing among patients with emotional disorders; and a study examining an innovative new cognitive-behavioral treatment for women suffering from perinatal grief. Other funded projects among students include the development of a novel program to promote adjustment and prevent anxiety and depression among newly committed gay couples.

It should be noted that CARD is not the only clinical facility within the Department of Psychology, since the department also supports a more traditional Psychological Services Center that services a broader range of psychopathology, beyond the emotional and related disorders. These clinics work closely together.

Once again, facilities such as these are now widely available in graduate and professional schools across the country and provide the fullest realization of Shakow's vision by clearly integrating theory and research with ongoing clinic work and providing a clear opportunity for a focus on clinical subject matter for required research projects. In this context, the imagination of trainees is given free rein and projects range from characterizing psychopathology and its various manifestations, to the full range of treatment development and evaluation.

### *Assessing Quality and Competence*

Finally, reflecting on the last theme of Shakow's vision, developing more objective standards for evaluating competence, the field has come a long way. In Chapter 8, Grus describes the "competency initiatives" that are either in place or in development to evaluate training programs or individuals within those programs. Here one finds a decidedly growing emphasis on the measurement of learning outcomes among doctoral students within the framework of identified core competencies. These themes have been in development for a number of years now (Kaslow, 2004; Kaslow et al., 2006). Assessing quality of services through improvements in assessment and the development of "outcomes assessment" will be taken up in the next section. In summary, by 2009 Shakow's proposal for training in clinical psychology had been realized, or is well on its way to being realized.

### Psychological Assessment in 1969

Shakow subsumed most aspects of psychological assessment under the term "diagnosis," but he makes it clear that, in addition to classification, the process includes descriptive and interpretive data gathered by the psychologists based largely on objective methods in the service of helping to understand both the individual and his or her disorder.

> On examination, this diagnostic contribution is found to be of three kinds: (1) The description of what the patient in his various conditions is like in certain relevant psychological functions, that is, *what he is*. (2) The implications that the psychological studies have for therapeutic (education, vocational, personality, etc.) policy, that is, *what to do*. (3) The determination of the effects of whatever therapy may have been used on psychological functions, that is, the evaluation of *what has been done*.
> (*Shakow*, 1969, p. 44)

As one can see, the general functions of psychological assessment outlined by Shakow are still very relevant today. Providing objective and

psychometrically sound descriptions of psychopathology and related psychological functions, including personality and neuropsychological processes, remains an important aim of psychological assessment, as does Shakow's second goal of providing reasonable prognostic information and interventions likely to achieve desired results. But the third goal articulated by Shakow was often overlooked in those days; that is, monitoring the outcomes of interventions.

In fact, Shakow notes that, although the three overarching goals of assessment are distinct, psychologists in that era used essentially the same tests and strategies to collect data in each of the three areas, as reflected in the standard psychological test battery of the day. Typical issues that psychologists were asked to address, particularly in hospital settings, included IQ levels; assessment of cognitive deficits such as amnesia, aphasia, agnosia, etc.; the diagnosis of various types of psychoses; and, of course, the assessment of personality characteristics. Shakow also notes that much of psychological assessment went on in "departments" of psychology in hospitals, to which patients were referred by psychiatric staff. In these cases, patients would often be referred for "psychologicals" and other laboratory testing, with the understanding on the part of psychiatric staff that the results would be used by psychiatrists to make informed decisions on diagnosis and treatment. Shakow remarked that viewing the psychology laboratory as a purely technical service, like, for example "blood work," was a position that "should be discouraged and actively fought" (Shakow, 1969, p. 45). This was an all-too-common perception of the role of psychology in those days and one that the present author experienced (and actually fought) in a hospital setting in the early 1970s. Thus, whereas Shakow differentiated and articulated the goals of assessment in a thoughtful manner, the process of psychological assessment in that era was actually characterized by a largely undifferentiated, standardized battery of psychological tests that varied little from individual to individual and was viewed as just one more set of laboratory results to assist the psychiatrist in case formulation and treatment planning. Interestingly, the nomothetic concept of "diagnosis" as we know it today was an imprecise process widely viewed as providing little value to the case formulation process. This was due to the demonstrated unreliability and lack of validity of the second edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) (American Psychiatric Association, 1968).

## Psychological Assessment in 2009

A quick perusal of the table of contents in this handbook reveals several chapters devoted exclusively to specialized psychological assessment. These chapters include discussions of interviewing and case formulation (Chapter 12), diagnosis and personality assessment (Chapter 13), clinical neuropsychology (Chapters 26 and 30), and tailored assessments within a variety of specialized contexts such as forensic and primary care settings (Chapters 27 and 29). But perhaps the most substantial development in recent years has been the extension of evidence-based concepts to the field of assessment, as described in some detail in Chapter 5 (Hunsley & Mash, this volume). Of course, considerable research ensued over the decades since 1969 on specific psychological tests and measures, and psychology became identified with a strong focus on psychometrics, a methodology that has been well worked out over the decades. Even for strategies that might seem less amenable to empirical evaluations, such as projective tests, there is substantial agreement within psychology on the importance of collecting and analyzing appropriate psychometric data, despite the fact that significant disagreements on the interpretation of those data may exist (Barlow, 2005; Exner, 2001; Wood, Nezworski, Garb, & Lilienfeld, 2001). Nevertheless, there was still something missing. What was missing was information and hard data on the usefulness of contemporary assessment practices for effectively formulating cases, planning treatment, or monitoring treatment outcomes. Thus, psychologists could choose psychometrically sound tests or assessment procedures, but there was little research on whether this process was actually contributing to desired outcomes.

This began to change over the past decade due to increased sensitivity to issues of accountability, as well as because of the need to conduct assessment research that is more directly related to treatment provision. All of this occurred, of course, in the context of the movement towards evidence-based health-care practices in general (APA, 2006; Institute of Medicine, 2001). As Hunsley and Mash (this volume) remark:

[Evidence-based assessment (EBA)] . . . is an approach to clinical evaluation that uses research and theory to guide the selection of constructs to be assessed for a specific assessment purpose, the methods and measures to be used in the assessment, and the manner in which the assessment process unfolds. Evidence-based assessment

involves the recognition by the psychologist that, even when data from psychometrically strong measures are available, the assessment process is inherently a decision-making task in which the psychologist must iteratively formulate and test hypotheses by integrating data that may be incomplete or inconsistent. As a result, a truly evidence-based approach to assessment involves an evaluation of the accuracy and usefulness of this complex decision-making task in light of potential errors and biases in data synthesis and interpretation, the costs associated with the assessment process and, ultimately, the impact the assessment had on clinical outcomes for the person(s) being assessed.

In fact, EBP initially focused largely on interventions. But when applied to psychological assessment, EBP highlights two somewhat different issues that shift the focus from the data-based evaluation of assessment instruments using psychometrically sound procedures.

The first issue relates to the greatly increased focus on understanding the nature of various psychopathologies as part of an effort to develop new and more precisely targeted interventions. Thus, assessment procedures and strategies, beginning with newly developed semistructured diagnostic interviews, have now been adapted to assess more thoroughly the intricacies and subtleties of various forms of psychopathology as our understanding of the nature of psychopathology deepens. For example, domains for assessment in the anxiety disorders necessarily differ from domains that might be assessed among individuals with depression, schizophrenia, or personality disorders (Antony & Rowa, 2005; Widiger & Samuel, 2005). Even issues outside of the usual boundaries of psychopathology, at least as defined by DSM, such as couples stress, require a more focused, conceptually based framework for assessment (Snyder, Heyman, & Haynes, 2005). Obviously, this is a substantial departure from simply administering a standardized battery of tests to individuals presenting for treatment, without regard to presenting psychopathology.

The second issue underscores that these strategies are closely linked to existing treatment options, with the expectation that progress will be monitored in each of the crucial domains to the point of outcome. Again, this was a stated goal of assessment from Shakow's perspective in 1969, but because of the commonly accepted standardized battery of tests of that era, this goal was seldom achieved or even pursued. It is worth noting, however, that this emphasis on ongoing outcomes assessment facilitates an interactive process that will improve treatment outcome, and there is some evidence already that this occurs (Lambert et al., 2003).

In summary, we have progressed from assessment based on a generalized comprehensive battery of tests without regard, for the most part, to presenting issues or problems, to a more evidence-based assessment process highlighting close integration with emerging conceptions of psychopathology. In addition, broad-based, ongoing outcomes assessment systems are increasingly required for EBP on the part of health-care policy makers.

Advances in psychological assessment are also greatly dependent on a broader and deeper understanding of psychopathology or related psychological processes that are the subject of assessment. This broader and deeper understanding is most evident in the radical changes in widely accepted systems of nosology over the decades. In 1980, the third edition of the DSM (DSM III) (APA, 1980) was published, reflecting a more empirical approach to classification of psychopathology. This document was updated in 1987 (DSM III-R, APA), 1994 (DSM-IV, APA), and 2000 (DSM IV-TR, APA), and the fifth edition of the DSM (DSM V) will appear in 2013. It is noteworthy that psychologists have played an increasingly large role in the development of this diagnostic system; for example psychologists comprised approximately half of the membership of the various work groups writing DSM-IV, and four psychologists (including Peter Nathan, editor of the Oxford Library of Psychology, of which this handbook is one volume, as well as the author [David H. Barlow]) were members of the Task Force that made all final decisions (APA, 1994). For DSM V, psychologists have taken the lead in beginning to move the system away from a psychometrically unsatisfactory prototypical categorical approach to a more dimensional approach (Brown & Barlow, 2009; Leyfer & Brown, Chapter 14, this volume; Widiger & Edmundson, Chapter 13, this volume). Although this rather radical revision will not be complete for DSM V, a wide consensus exists that dimensional approaches to nosology represent the future, and that increasingly sophisticated, empirically based psychological approaches to diagnosis and assessment will comprise the major mechanism in achieving this goal.

### Therapy in 1969

Interestingly, the practice of psychotherapy in 1969 was perhaps the most underdeveloped role for psychologists for several reasons (see also Routh,

Chapter 2, this volume). First, very few psychologists were allowed to practice psychotherapy, and when they did, it was often under the direct supervision of a psychiatrist or another physician. This reflected the widely held position at that time that, since one could not separate mind and body (an assumption that has proved increasingly true over the decades), then one must have comprehensive training in both basic biological sciences (e.g., anatomy, biochemistry) as well as psychiatry to practice psychotherapy (an assumption that very few would hold today). A second reason was that very little was known about psychotherapy in terms of the types of problems that would respond to therapy, the psychological techniques and procedures one would use to accomplish therapeutic goals, and the necessary and optimal therapist qualities. Thus, Shakow recognized at that time the well-established social need for psychotherapists, but wondered just what sort of training would be necessary, and if this training should be preferentially associated with one of the mental health professions.

> My fundamental position . . . is that the practice of psychotherapy should not be determined by a person's particular discipline. Many years of observation in this area have led me to believe that so far as psychotherapy is concerned, the order of importance of the three factors integrally involved is first, the personal qualities of the therapist; second, the nature of the patient and his problem; and, third, the nature and adequacy of the therapist's training, especially in areas related to human psychology and motivation. Particular professional identification is not necessarily involved in these three.
> (*Shakow*, 1969, p. 64)

He goes on to remark that, upon referring a friend for psychotherapy, he would rely far more on the personal qualities of the therapists than on their professional training, while admitting that it would be hard to define these personal qualities in a standard manner that would be useful for research. Although Shakow stipulated that one very important topic for research by psychologists should be psychotherapy, Shakow's preferred directions for psychotherapy research are perhaps least developed due, of course, to the clear emphasis in that era on the more highly developed area of psychological assessment and the construction of psychological tests. It would be another decade before psychologists were generally afforded the privilege of practicing psychotherapy independently, and even then this was seldom possible in hospital or other clinical settings, dominated as they were by the medical profession.

Shakow did have some ideas about the ideal training for psychotherapists that would occur in independent institutes, perhaps located within a university or other clinical setting, but he clung to the idea that this institute should be open to all professions with an interest in psychotherapy and that some of the didactic material would come from contributions of the humanities and the biological sciences, as well as the core mental health professions. Although Shakow himself identified with psychoanalytic thinking, as did most mental health professionals in those days, he regarded psychoanalytic institutes as narrowly construed and not an ideal model for training in psychotherapy. Of course, research on the variety of evidence-based psychological procedures that would find their way into the armamentarium of psychologists engaged in treatment was only just beginning.

In fact, results from some of the first research studies of psychotherapy at that time were very discouraging, in that therapy had relatively little effect either positive or negative when results from treatment groups and comparison groups not receiving therapy were examined (Barlow & Hersen, 1984; Bergin, 1966; Bergin & Strupp, 1972). Classic early studies, such as the Cambridge Somerville Youth Study (Powers & Witmer, 1951), which took decades to complete, arrived at this finding, as did other early efforts involving large numbers of patients treated in approximations of randomized, controlled clinical trials (Barron & Leary, 1955). More process-based research conducted on large numbers of outpatients to the point where outcomes were examined came to similar conclusions. The eminent psychotherapy researcher Lester Luborsky and his colleagues (1975) pointed out the lack of specificity of any psychotherapeutic procedures. In this era, Eysenck (1952; 1965) published his famously controversial thesis based on data from crude actuarial tables that outcomes from psychotherapy across a heterogeneous group of patients were no better than rates of "spontaneous" improvement without psychotherapeutic intervention over varying periods of time. Although this conclusion was outrageous to many who were convinced of the power of psychotherapy, in that it seemed to fly in the face of clinical experience, it was enormously impactful since it was difficult to rebut based on the dearth of evidence available.

Thus, advocates of psychotherapy in those early years were faced with a paradox. On the one hand,

many psychologists assumed that training in psychotherapy was important, although as noted by Shakow, there was no consensus on how to do it. On the other hand, psychotherapy research of the day, such as it was, could not substantiate the assumption that psychotherapy had any effect whatsoever, either positive or negative.

This state of affairs began to change in 1966, with the publication of a seminal article by Allen Bergin (1966) in the *Journal of Abnormal Psychology* entitled "Some implications of psychotherapy research for therapeutic practice" (see Barlow, 2010). What Bergin concluded, based on a further analysis of some preliminary data first published in Bergin (1963) was that "Psychotherapy may cause people to become better or worse adjusted than comparable people who do not receive such treatment" (p. 235). Bergin found, as did Eysenck, that "Typically, control subjects improve somewhat with the varying amounts of change clustering around the mean." But, contrary to Eysenck's conclusions, Bergin observed, "On the other hand, experimental subjects are typically dispersed all the way from marked improvement to marked deterioration" (Bergin, 1963). Thus, the data indicated that psychotherapy could make some people considerably better off than comparable untreated patients. This was the first objective evidence against Eysenck's assertion that all changes associated with psychotherapy were due to spontaneous remission. As Bergin noted: "Consistently replicated, this is a direct and unambiguous refutation of the oft-cited Eysenckian position" (p. 237). From a historical perspective, this was a very important conclusion from the point of view of both science and policy, but did little to provide direction to the fledgling endeavor of psychotherapy.

Bergin (1966), in the process of articulating his influential argument, also described the substantial deficits in extant studies of psychotherapy at that time and, in so doing, began to pave the way for marked improvements in psychotherapy research methods to unfold in the coming decades (Barlow, 2010). He observed, for example, that experimental and control groups were often not well matched with differences in initial severity on various measures, a common finding. He also pointed out that individuals assigned to control groups were often subject to substantial nonexperimental influences, including therapeutic intervention of various sorts occurring outside the context of the clinical trial. To account for these influences, he suggested the need to carefully ascertain if control groups were indeed acting as controls and/or to directly measure the effects of nonexperimental influences that might affect outcomes. He also presented some preliminary data showing that training was an important variable if therapists were indeed to deliver the treatment as intended, contributing to what we now refer to as *treatment integrity* of the intervention under study (Hayes et al., 1999). This issue arose in some earlier studies in which therapists had little or no training, and it was unclear just what they were doing (Powers & Witmer, 1951).

In addition to these critiques of existing studies, Bergin and Strupp, in 1972, went on to suggest more proactive recommendations on the future conduct of psychotherapy research, recommendations that were to have substantial impact. One of the observations focused on the substantial individual differences among patients in these studies, particularly patients with emotional or behavioral disorders. They suggested that attempts to answer basic questions on the effectiveness (or ineffectiveness) of a specific treatment for a specific individual would be impossible when applying broad-based and ill-defined treatments such as *psychotherapy* to a heterogeneous group of clients only vaguely described using such labels as *neurosis.* This heterogeneous approach also characterized meta-analyses in that era (Smith & Glass, 1977). Thus, Bergin's review suggested that asking "Is psychotherapy effective?" was probably the wrong question. Bergin and Strupp (1972) cited Gordon Paul (1967), who suggested that psychotherapy researchers must start defining their interventions more precisely and must ask the question, "What specific treatment is effective with a specific type of client under what circumstances?" (p. 112).

### Therapy in 2009

Although Shakow foresaw EBP, even he would be greatly surprised by the radically different nature of psychotherapy and psychological treatments in 2009, much of it made possible by improvements in the methods of psychotherapy research. In addition to experimental design considerations, methodological improvements included a deeper understanding of psychopathology, allowing for the development of more targeted psychological treatments; a greater specification of psychological treatments, often in the form of flexible manuals to better define ongoing therapeutic operations; and a new emphasis on comparative effectiveness research. What follows is a brief discussion of the development of treatment manuals and clinical practice guidelines, and a growing emphasis on change in the individual versus

average change in the group. To illustrate some of the trends in therapy research over the decades, I also present an account of the development of a new psychological treatment for panic disorder as it occurred over the last 20 years in our Center.

## Treatment Manuals and Clinical Practice Guidelines

The initial impetus for the development of treatment manuals came from psychodynamic psychotherapy researchers who, in the early 1960s, began to test broadly the effectiveness of specific treatments in controlled outcome studies. Looking to demonstrate that psychological interventions could withstand rigorous scientific investigation, similar to that of existing pharmacological treatments (Luborsky & DeRubeis, 1984), scientist-practitioners realized that they needed treatment tools that would allow for systematic replication and comparison. Wilson (1996) more specifically pointed out that treatment manuals sought to eliminate any "substantial variability" associated with "clinical judgment" or intuition that might cause one therapist to proceed in a very different manner from another. Thus, to study the effectiveness of these therapies, treatments were condensed into manuals that could then be reviewed and used across studies. Many researchers hoped that by utilizing treatment manuals presented in this fashion, psychological interventions would be able to withstand the methodological constraints of research protocols. More specifically, it was thought, "treatment manuals help support the internal validity of a given study by ensuring that a specific set of treatment procedures exists, that procedures are identifiable, and that they can be repeated in other investigations" (Dobson & Shaw, 1988). This was in contrast to the conduct of treatment outcome research prior to manualization, during which time specific therapeutic techniques were often not explained and thus could not be compared to other treatments or be replicated by other investigative groups, as in early studies already described.

Another push to develop specific treatment manuals came from the founding of the Agency for Health Care Policy and Research in the United States in 1989 (now called the Agency for Health Care Research and Quality). The sole purpose of this Agency was to facilitate the identification of the effectiveness of specific treatment strategies for specific disorders, with the aim of increasing the quality and reducing the cost of health care (Barlow, 1996). One major mechanism of accomplishing this goal was the creation of clinical practice guidelines that explicitly articulate the optimal strategies for assessing and treating a variety of psychological disorders based on an up-to-date review of evidence. In 1995, the APA promulgated a template for evaluating and setting minimum standards for these guidelines (Barlow, 1996), and these criteria were revised in 2002 (APA, 2002). Interventions recommended in these clinical practice guidelines are typically based on two specific factors as derived from the APA template: (a) *efficacy*, or internal validity of the specific treatment, the determination of which is based on the results of a systematic evaluation of the intervention in a controlled setting; and (b) *effectiveness*, or clinical utility of the treatment, which is based on the feasibility, general relevance, and cost effectiveness of the intervention actually being delivered in a local setting. Based on these equally important and rigorous bases of evidence, the development of treatment manuals that could produce the necessary evidence was encouraged. As a result, manual-based treatments were incorporated in early schemes as one of the major components of evidence-based service delivery (Barlow, 2004).

## An Emphasis on the Individual

Although examples of evidenced-based psychological treatments for the full range of psychopathology can be found in appropriate chapters throughout this handbook, one concern frequently expressed focused on the "one size fits all" rigidity seemingly inherent in the administration of manualized treatment. This issue derived directly from the nature of psychotherapy research emphasizing, as it did, the average response of a treated group.

In fact, early on, leaders in psychotherapy research, such as Bergin and Strupp, suggested that a more valid tool for looking at the effects of psychotherapy would involve a more intensive study of the individual. "Among researchers as well as statisticians there is a growing disaffection from traditional experimental designs and statistical procedures which are held inappropriate to the subject matter under study" (Bergin & Strupp, 1972, p. 440). They recommended the individual experimental case study as one of the primary strategies that would move the field of psychotherapy research forward, since changes of clinical significance could be directly observed in the individual under study (followed by replication on additional individuals). In such a way, changes could be clearly and functionally related to specific therapeutic procedures. These ideas contributed to the development of single-case experimental designs for studying behavior change (Barlow, Nock, & Hersen,

2009; Hersen & Barlow, 1976). These designs, then and now, play an important role not only in delineating the positive effects of therapy but also in observing more readily any deleterious effects that may emerge, thus complementing efforts to extract information on individuals from the response of a group in a clinical trial (Kazdin, 2003).

This emphasis on individual change of clinical and practical importance contributed to a revision of the ways in which data from large between-group experimental designs (clinical trials) were analyzed (Kazdin, 2003). Specifically, over the ensuing decades, psychotherapy researchers began to move away from exclusive reliance on the overall average group response on measures of change and began highlighting the extent of change (effect sizes and confidence intervals), whether the change was "clinically significant," and the number or percentage of individuals who actually achieved some kind of satisfactory response (with a passing nod to those who did not do well) (Jacobson & Truax, 1991). Data-analytic techniques also became more sophisticated, powerful, and valid, with a move away from comparison of means among groups to multivariate random effects procedures, such as latent growth curve and multilevel modeling, which evaluate the extent, patterns, and predictors of individual differences in change (Brown, 2007).

In addition to improved delineation and definition of the actual psychotherapeutic procedures undergoing evaluation, as noted earlier, an equally important development was a greater specification of those psychopathological processes that most often comprised the targets of change efforts. Over the ensuing decades, the very nature of psychopathology in its various manifestations became increasingly well understood and defined, based on research in this area. This led to the appearance of nosological conventions through which psychotherapy researchers could begin to reliably agree on what was being treated and how to measure change, as described earlier (Barlow, 1991). Investigators increasingly made use of this information to assess both the process and outcomes of interventions (Elkin et al., 1989). Thus, by the 1980s, the field was now specifying and operationalizing psychotherapeutic procedures, as well as associated therapist, client, and relationship factors, and also specifying and measuring the targets of treatments in the form of identifiable psychopathology in a way that highlighted individual differences in response. By the 1990s, publications of large clinical trials, some begun 10 years prior to publication, rapidly grew in number. In the clinic, this new emphasis facilitated greater attention to flexibility in the administration of evidenced-based manualized treatments based on case formulation and a move toward individualized treatment modules (Chorpita, Bernstein, & Miranda, Chapter 11, this volume; Spring & Neville, Chapter 7, this volume). These trends and strategies are next profiled in an account of the development of a psychological treatment for panic disorder in our Center (Craske & Barlow, 2008) and the relative efficacy of this treatment.

## The Development of a Psychological Treatment for Panic Disorder

In the 1980s, a physical problem—some kind of a brain dysfunction—was thought to cause panic disorder. The best candidate was a "chemical imbalance," which was believed to cause heightened sensitivity in the brainstem. By the 1990s, research had ruled this out as the sole underlying cause (Barlow, 2002; Gorman et al., 1990), and investigators agreed that an interacting web of biological and psychological factors contributed to the onset of panic disorder (Bouton, Mineka, & Barlow, 2001).

When the cause of panic disorder was thought to be solely biological, drugs were the first choice for treatment. In the 1980s, the most popular drugs for panic disorder were high-potency tranquilizers, known by brand names such as Xanax and Klonopin. These drugs could be effective for panic disorder, but many patients developed dependence, such that attempts to stop taking them produced serious side effects. Because of this problem with dependence and addiction, other drugs, such as selective serotonin reuptake inhibitors (SSRIs), became the preferred drugs for treating panic disorder. These drugs include brand names such as Paxil and Prozac. Approximately 50% of patients with panic disorder respond at least somewhat (and some very well), as long as they continue to take the medication. But relapse rates are high once the medication is stopped (Craske & Barlow, 2008).

Around 1990, my colleague, Michelle Craske, and I developed a psychological treatment for panic disorder that focused directly on the sensitivity of these individuals to their own physical sensations, such as fluctuating heart rate, skin temperature, and dizziness (Barlow & Craske, 2007; Craske & Barlow, 2007). In people who are susceptible, these sensations are very frightening because they come to trigger the next panic attack through the psychological process of learning and association called *conditioning* (Bouton et al., 2001).

Based on this insight, we experimented with a treatment in which individuals with panic disorder were exposed to mild versions of the physical sensations. In the protected setting of our clinic, we had them exercise vigorously to produce fluctuations in heart rate, spin around in a chair to produce slight dizziness, and so forth. We decided which symptoms would be induced based on an assessment of the mix of physical sensations that were closely associated with a particular patient's panic attacks (these vary from one person to another).

In a psychological process called *extinction*, our patients learned, by experiencing these physical sensations repeatedly, that the sensations didn't lead to a terrible outcome, such as a heart attack. Of course, their rational self knew this all along, but the emotional brain, where these fear responses reside, tends to override the rational brain in cases of panic or any emotional disorder. Hence, these specialized treatments to reach the emotional brain.

To assist in strengthening the "rational brain," the patients' basic faulty attitudes and perceptions about the dangerousness of these sensations are also identified and modified. Patients might also be taught calming techniques, such as breathing and meditation, to help them cope with stress and anxiety in general. In a number of subsequent studies, we demonstrated that this treatment, a cognitive-behavioral approach called *panic control treatment* (PCT), is effective for panic disorder (Barlow & Lehman, 1996).

My colleagues and I then tested the hypothesis that combining drugs and psychological treatments might prove more effective than either individual treatment alone. We conducted a large clinical trial and treated 312 patients with panic disorder at four different sites. Two of these sites were known for their expertise with drug treatments, and two were known for their expertise with cognitive-behavioral therapy (CBT). Patients at all sites were administered either the psychological or drug treatment alone, or in combination, along with appropriate comparison conditions such as a drug placebo condition. The experiment was also double-blind, which means that neither the therapists nor the patients knew whether they were getting the actual medication or the placebo (sugar) capsule (Barlow, Gorman, Shear, & Woods, 2000).

We found that both the drug and the psychological treatments were effective, as we expected, with each better than the placebo. But, much to our surprise, the combination treatment was not any better than the individual treatments. Thus, our hypothesis was not proven, and the widespread practice of administering both treatments simultaneously for panic disorder was called into question. Furthermore, after all treatments were stopped, the psychological treatment was found to be more durable. That is, fewer people relapsed over a period of 6 months after treatment was stopped in those patients who had the psychological treatment either alone, or combined with placebo. In the two conditions in which patients received an active drug (drug alone or drug plus psychological treatment), more people relapsed.

We concluded from this evidence that combining treatments offered no advantages and that, given a choice, the preference would be for the psychological treatment because it was more durable and less intrusive. (Drug treatments are almost always considered more intrusive than psychological treatments due to side effects or drug interactions that could occur.) Of course, some patients prefer to take a drug, or the cognitive-behavioral treatment may not be available, in which case drug treatment is a good alternative.

In a second study (Barlow, 2008), colleagues and I evaluated best strategies for maintaining long-term health after treatment. We began with the working hypothesis that once patients received CBT and were essentially cured, they would not need any further treatment sessions. We based this assumption on the view of most of our therapists that no further intervention was needed if patients had learned all the concepts that the therapists had taught them and had implemented them well in daily life.

But not all of our therapists agreed. Some argued that occasional booster sessions would prove useful in preventing relapse over the long-term in this chronic condition. To test this notion, we treated 256 patients with panic disorder and agoraphobia of varying degrees of severity, using the same CBT that we employed in our first study. Many of these patients (157, or 61.3%) did very well with treatment and were essentially cured. To evaluate the advantage of booster sessions, half of these patients ($n = 79$) went on to receive nine additional sessions, spaced every month for 9 months, and they then were followed for another year with no further treatment. The other half of the patients ($n = 78$) received no further treatment.

When the results were assessed after the 1-year period without any treatment, the majority view was proved wrong. That is, there *was* an advantage to having booster sessions. Among the group that did not have booster sessions, 18.0% had some

relapse or recurrence of panic disorder during the 1-year follow-up and 82.0% stayed well. By contrast, only 2.7% of the group that experienced booster sessions evidenced a relapse or recurrence during that year, and fully 97.3% stayed well. This significant difference demonstrates the value of some continued attention to these patients, who are, after all, suffering from a chronic condition that waxes and wanes.

Of the remaining patients—individuals who did not meet our criteria for "responding" to treatment to the point at which they were essentially cured—some dropped out along the way for a variety of reasons, such as moving away or just feeling they didn't need treatment anymore. Others finished treatment with varying responses from just missing our criteria for being all but "cured" to having no benefit whatsoever. In this latter group, we evaluated the benefits of then giving them a medication for panic disorder (paroxetine) and, although the results haven't been fully analyzed yet, sequencing the treatments in this way looks like a promising treatment approach.

Scientific discoveries about the nature of panic disorder led us to develop a specifically tailored psychological treatment. The experiments I've described confirm that we have an effective psychological treatment for panic disorder—a treatment that has become a first-line choice based on recommendations from National Health Services around the world. Of course, we still have a long way to go to make our treatments powerful enough to benefit the largest number of people.

Interestingly, our studies also confirm that a number of our assumptions were incorrect. First, we proved ourselves wrong that combining drug and psychological treatments would be better than simply providing patients with one treatment or the other. Second, we now know that individuals who respond to treatment need further attention after treatment has ended to ensure that they have the best chance to stay well. Without close scientific examination of the effects of psychological treatments, we would have been unaware of these important treatment issues, and patients with panic disorder would not be getting the best care possible.

## Conclusion

Clinical psychology was a work in progress in 1969, and it continues to be a work in progress today. I have chosen to recount David Shakow's vision in three areas—training, assessment, and therapy—since his views of clinical psychology on these issues circa 1969 make for a fascinating perspective on directions and progress of clinical psychology over the ensuing 40 years. Generally, the accuracy of Shakow's vision for the future is remarkable and attests to his status as one of the founding fathers of clinical psychology. But, of course, he could not have foreseen the explosive growth of the field and the substantial changes that would evolve in all of their detail despite accurately forecasting the broad outlines of these changes. It is perhaps in the area of training that Shakow has come closest to the mark in that a more fully realized Scientist-Practitioner model of clinical practice dominates the field of training. As I noted, in view of the ascendance of EBP, it seems that this model of training for clinical practice will become an even more uniform template for the training of clinical psychologists in the years to come. But it should also be noted that this does not mean that psychologists emanating from Scientist-Practitioner programs will necessarily be trained in the intricacies of the scientific method to an extent necessary to become clinical scientists. Continuing to model Shakow, some of my own predictions for the future of our science and profession can be found in Chapter 39, the concluding chapter. There, my coauthor and I hazard what might seem to be some rather radical predictions for the development of training in clinical psychology.

In the area of assessment and diagnosis, a component of EBP, evidence-based assessment, is beginning to exert considerable influence and is very likely the wave of the future. Although Shakow did not envision the enormous influence psychologists would have on creating an empirically based nosology, nor did he necessarily envision the deep and broad increases in our knowledge of the nature of psychopathology and psychological processes, it is clear that his vision of the general function of assessment has stood the test of time. In Chapter 39, we also speculate on future developments to the relationship of the nomothetic process of diagnosis and classification to the more idiographic process of functional assessment. These two processes take us well beyond the status of psychological assessment in 1969, which was largely relegated to the development of psychometrically sound psychological tests, although this remains an extraordinarily important contribution of psychologists to this day.

Finally, the greatest change has occurred in the development of psychological treatments. The example of treating panic disorder described earlier in the chapter is but one of many equally fascinating examples of the development of evidence-based psychological

treatments and was chosen simply because I am most familiar with it. Other excellent examples are found throughout this handbook and represent the most remarkable advances in my own 40-year odyssey. Of course, we are just at the beginning stages of the development of evidence-based psychological interventions. In Chapter 39, the concluding chapter, we also provide some predictions on the further recognition, development, and dissemination of psychological treatments and the kinds of efforts and trends that are likely to occur in service of these goals. To take one example, we suggest that the specific treatment of panic disorder developed in our clinic ("panic control treatment") is unlikely to be practiced in any kind of a systematic way in 10–15 years time. By that time, new psychological treatments based on our ever-deepening knowledge of psychopathology will likely focus on common therapeutic principles applicable to fundamental psychopathological processes found across the full range of emotional disorders. Similar developments will take place in other broad areas of psychopathology, which will increasingly be conceptualized along dimensions of traits and temperaments, suggesting new, more fundamental targets for treatment.

Of course, many of these developments are relatively new and do not yet characterize in any comprehensive sense the current practice of psychotherapy, which is very heterogeneous indeed. In the meantime, standing on the shoulders of the giants in our field over the past 40 years, the chapters in this handbook represent a breadth and depth of knowledge in the ever-expanding field of clinical psychology that would make David Shakow, and all of our forebears, proud.

# History, Professional Issues, and Emerging Approaches to Psychopathology and Treatment

# A History of Clinical Psychology

Donald K. Routh

## Abstract

To be memorable, a history such as this might best be organized under a small number of headings. Accordingly, this chapter is structured around the work of seven pioneers who arguably had the greatest influence on the development of the field. Lightner Witmer is generally considered to have founded clinical psychology in 1896 (McReynolds, 1987, 1997; Routh, 1996; Watson, 1956). Hippocrates was the ancient Greek founder of medicine, always a close professional cousin of clinical psychology and a scientific model for psychology in general. Theodule Ribot led the development of psychology as an academic discipline in 19th-century France, as one primarily focused on clinical issues. Alfred Binet, also in France, devised the first practical "intelligence" test in 1905; administering such tests was among the most common activities of early clinical psychologists. Leta Hollingworth was an early practitioner who played a large role in the development of organized clinical psychology beginning in 1917 (Routh, 1994). Sigmund Freud founded psychoanalysis, the first influential form of psychotherapy practiced by clinical psychologists, among others. Finally, Hans Eysenck was among the earliest to conceptualize behavior therapy and to promote the use of what have come to be known as evidence-based methods of intervention in clinical psychology.

**Key Words:** Binet, Eysenck, Freud, Hippocrates, Hollingworth, Ribot, Witmer

Clinical psychologists have become familiar figures in America and in many countries around the world (Swierc & Routh, 2003). Indeed, clinical work now seems to be the most common activity of psychologists. They carry out psychotherapy or other interventions with individuals, groups, and families. They engage in various kinds of clinical assessment of the mental and behavioral aspects of health problems. Many collaborate with other health professionals or act as consultants in clinics and hospitals. Clinical psychologists are frequently involved in educational activities, teaching in colleges or universities, and many are also engaged in research. Despite its familiarity, this field had its origins in 1896, not much more than a century ago. This chapter attempts to provide a vivid portrait of its roots.

## Hippocrates

To speak of "clinical" psychology is to invoke the medical metaphor of care at the bedside of the individual (the Greek word *klinein* refers to a couch or bed). In naming clinical psychology, Lightner Witmer thus alluded to the tradition of Hippocrates. Born on the Greek island of Cos about 460 BCE, Hippocrates is considered to be the founder of medicine. In using the word "clinical," Witmer implied that it is appropriate for psychology, like medicine, to attempt to help individuals.

Medicine is not only a profession but also a scientific field and, as such, served as a model for psychology in general. In comparing the Hippocratic writings to the previous Greek tradition of the god Asclepias, the most notable characteristic is Hippocrates' naturalism, the idea that the phenomena

of human illnesses can be understood and explained in scientific terms. A famous example concerns epilepsy, often labeled in ancient Greece as a "sacred" disease. Seizures were thus explained as possession of the body by some invisible spirit. In contrast, Hippocrates and his followers believed that epilepsy was no more divine than any other illness and that its causes could be understood in natural terms (Temkin, 1994).

In addition to the name of Hippocrates, so familiar to accounts of Western medicine, the origins of modern scientific medicine can also be traced to various sources outside Europe, for example, ancient China, India, Egypt, and various smaller indigenous groups. In China, the best known ancient source of medical wisdom is the *Yellow Emperor's Classic of Internal Medicine*, probably written in the late first century BCE. This book discusses such well-known concepts as yin and yang; the Five Elements; the effects of diet, lifestyle, emotions, and the environment on health; how diseases develop; and the principles of acupuncture (Veith, 2002).

In ancient India, Ayurvedic medicine evolved over several millennia and appeared in writing about 2,000 years ago. The Sanskrit term, *ayur* means "life," and the term *veda*, "science or knowledge." The Ayurveda describes the constitution of the body (*prakriti*) and the operation of life forces (*doshas*), made up of the elements ether, air, fire, water, and earth. Ayurvedic treatments rely heavily on the use of herbs and plants (Lodha & Bagga, 2001).

Our knowledge of ancient Egyptian medicine is fragmentary. Examples of well-known sources include the Edwin Smith Papyrus and the Ebers Papyrus. The Edwin Smith Papyrus was written in about the 16th century BCE, based on material from perhaps a thousand years earlier. It outlines a series of 48 traumatic injury cases, including a discussion of the physical examination, treatment, and prognosis of each. Of special interest to psychologists are its descriptions of the cranial sutures, meninges, external surface of the brain, cerebral spinal fluid, and existence of a pulse in cerebral blood vessels (Breasted, 1922). The Ebers Papyrus, written in about 1550 BCE, includes a description of mental disorders, including depression and dementia. Like Hippocrates, the ancient Egyptians seemed to think of mental and physical disorders in much the same terms.

It seems that the culture of just about every human group includes concepts of health and illness, including what psychologists consider to be mental disorders, as well as ideas about how these problems should be managed. The Florida Seminole tribe, to give a modern example, considers the role of its medicine people an important one, which requires about eight years of intensive training to master and requires extensive knowledge of herbal treatments (West, 1998).

Many of the founders and influential researchers in the modern academic discipline of psychology, including Wilhelm Wundt, William James, Hermann Helmholtz, and Ivan Pavlov, were physicians by education, but they were scientists and scholars rather than practitioners of medicine. Wilhelm Wundt (Witmer's teacher at the University of Leipzig), who is generally credited with founding the first psychology laboratory in 1879, was medically trained, but not a practicing physician. Wundt carried out research in psychology, edited a journal, wrote books summarizing research in the field, and trained many of the first generation of experimental (or "physiological") psychologists, including Americans as well as Europeans (Benjamin, Durkin, Link, Vestal, & Accord, 1992). Although he was primarily devoted to basic research in psychology, Wundt maintained an interest in what today might be called mental health issues. Among Wundt's students and research collaborators was Emil Kraepelin, one of the leading psychiatrists of Germany during the late 19th and early 20th centuries (Kraepelin, 1962). Kraepelin studied manic-depressive disorder and conceptualized "dementia praecox" (the mental disorder now termed schizophrenia). He established psychology laboratories in mental hospitals under his direction, and studied experimentally the effects of alcohol and morphine on human reaction time.

William James, who is considered to be the founder of modern psychology in the United States, was also trained as a physician, but chose not to practice medicine. James spent his career teaching physiology, psychology, and philosophy at Harvard University, and wrote the classic two-volume textbook on *The Principles of Psychology* (James, 1890). Like Wundt, James maintained an academic interest in what we would now call mental health, as manifested by his 1896 Lowell Lectures on Exceptional Mental States (Taylor, 1983).

Another example of the influence of medicine on general psychology is provided by the work of Hermann Helmholtz. Helmholtz was born in Prussia in 1821, and he went on to become a world-recognized figure in several scientific fields, including physics, physiology, medicine, and psychology (Cahan, 1993). In terms of contributions to psychology and what is now called neuroscience, Helmholtz was the first to actually measure the speed of the nerve

impulse in several different species. Some of his best-known scientific work on vision and hearing utilized his background in several areas, including mathematics, physics, physiology, and psychology. What is known as the Young-Helmholtz theory of color vision hypothesized the existence of three separate types of receptors in the retina for light of different wavelengths, corresponding to red, green, and violet. Subsequent research indeed demonstrated three different types of cone cells in the retina, with visual pigments responding to different wavelengths. In terms of the functioning of the auditory system, Helmholtz believed that the cochlea, the main sensory organ of the inner ear, worked something like a piano, with different strings vibrating to different frequency in sounds transmitted to it. Helmholtz also developed a theory of visual perception as an empirical process—in other words, one developed through experience. According to this theory, which continues to be influential, people engage in "unconscious inferences" in order to combine various cues about how far away objects are. During his time as a professor of physiology at the University of Heidelberg, Helmholtz served as supervisor to a younger colleague named Wilhelm Wundt. Thus, in effect, he taught some experimental psychology to the man who later became known as its "founder."

A final example of the influence of medicine on general psychology is provided by the career of the Russian scientist, Ivan Pavlov, who received the Nobel Prize for Medicine or Physiology in 1904, for his work on digestive processes. Born in 1849, Pavlov attended what was then called the Medical-Surgical Academy in St. Petersburg, the leading medical school of Russia. Rather than going into medical practice, though, Pavlov spent his career as a researcher. He developed a special chronic physiological procedure, isolating a separate pouch within a dog's stomach so that digestive juices could be collected from it. He was thus able to carry out a systematic program of research on the neural control of digestive processes in the dog. His laboratory worked out an arrangement in which about 15 medical students at a time seeking doctoral degrees could be employed as research collaborators, a veritable factory of physiologists (Todes, 2002). By about 1902, even before he received the Nobel Prize, Pavlov had decided to change the overall direction of his research toward work on what became known as "conditioned reflexes." Thus, he began what the world came to recognize as pioneering research in experimental psychology. Like humans and other animals, dogs do not just salivate when they actually eat, but as a result of just smelling the food, looking at it in a dish, or the appearance in the room of the person who is about to feed them. Pavlov used salivation to study processes now familiar to all psychologists, including conditioning, extinction, generalization, discrimination, and many others, including the disturbed behaviors called "experimental neuroses" that can be observed in the laboratory setting. His *Lectures on Conditioned Reflexes* were translated into English in 1927, and the concepts of conditioning have been influential throughout the world since that time.

Unquestionably, the psychological research of scientists such as Helmholtz and Pavlov has great "clinical" relevance, for example in ophthalmology and gastroenterology, but these workers are not usually regarded as clinical psychologists, because their work was not directly concerned with mental health, and they were not directly involved in trying to help individuals.

## Theodule Ribot

Although clinical psychology as such did not originate there, France had a central role in the development of both psychiatry and neurology. French psychology, when it did develop under the leadership of Theodule Ribot (1839–1916), had its principal focus on the study of psychopathology (Nicolas & Murray, 1999). The French physician Philippe Pinel is generally considered to be the father of psychiatry as a medical specialty (Riese, 1969). Not long after the French Revolution of 1789, Pinel joined Jean-Baptiste Pussin in removing the chains from the mental patients in the Bicetre and Salpetriere hospitals in Paris. During the 19th century, the eminent neurologist Jean Charcot also worked at the Salpetriere Hospital, where he pioneered in the use of hypnosis in the treatment of patients with "hysteria" (Guillain, 1959). Ribot, the founder of French psychology, had Charcot as one of his teachers.

Ribot wrote an influential book about what was happening in psychology in Germany and England, and founded a journal to introduce his French colleagues to the psychological research going on in these countries. In 1881, Ribot published a second book, *Disorders of Memory*. Summarizing the existing research on memory, he developed the generalization now known as "Ribot's Law," stating that, in retrograde amnesia associated with brain damage, it is the most recent memories that tend to be lost, sparing the older ones. In some of his other writings, Ribot described the phenomenon of *anhedonia*, a loss of pleasure in daily activities, which is typical of

persons experiencing mental depression and schizophrenia. In 1885, Ribot was made professor of psychology at the Sorbonne, and in 1888, he was given a chair in experimental and comparative psychology at the prestigious College de France.

The pattern in France was for any psychologist who wished to provide clinical services to individuals to go to medical school and become a neurologist or psychiatrist. Thus, Pierre Janet did his dissertation in psychology in 1889, under Ribot, and then completed a medical thesis under Charcot in 1892, on the mental states of persons with hysteria. It was Janet who coined the term "dissociation," and who first described multiple personality disorder. He also described "psychasthenia," better known today as obsessive-compulsive disorder. In addition, Janet developed a variety of psychotherapy techniques, considered by some to be an important rival of Freud's psychoanalysis (Janet, 1924).

## Lightner Witmer

The term "clinical psychology" was first used in an article by Lightner Witmer (1867–1956), a psychology professor at the University of Pennsylvania, in the inaugural issue of a new journal he began to publish in 1907, *The Psychological Clinic*. Its 19th-century founders considered the modern discipline of psychology to be a science analogous to physiology; indeed, it was often labeled as "physiological psychology" for that reason. Witmer's idea was simply that if this new science was worthwhile, it ought to be possible to use its principles to help individuals with various problems. In other words, he thought that psychology should be an area of professional practice, as well as a science, and history has vindicated this concept.

The work of Witmer had some of its roots in France, but not in the work of Ribot or Janet. Witmer was most interested in the attempts of J. R. Pereira and J. M. Itard to teach language to nonverbal children, including the so-called Wild Boy of Aveyron, and the procedures developed by Edouard Seguin to remediate children with intellectual disabilities (Routh, del Barrio, & Carpintero, 1996).

Before going into psychology, Witmer taught English in a Philadelphia preparatory school (McReynolds, 1997). As a teacher, he encountered a student who was progressing poorly in his schoolwork. Witmer tried to help the youngster overcome these academic problems and learned that the boy had specific difficulty with language, including speaking and reading. The boy seemed to benefit from Witmer's efforts in his behalf.

Like many psychologists of his generation, Witmer went abroad to study and eventually obtained his doctorate under the direction of Wilhelm Wundt at the University of Leipzig. Wundt trained more American doctorate students in psychology than any other individual in the 19th century. When Witmer returned to the United States after his graduate training, he took a position as a faculty member in psychology at the University of Pennsylvania.

In 1896, Witmer founded the first psychology clinic at the University of Pennsylvania. Margaret McGuire, a student in one of his classes, was a schoolteacher with a student who had difficulty in learning to spell. She asked her professor if he could possibly help with this problem. Witmer reasoned that if this new scientific psychology was really worthwhile, it ought to be able to help with such problems. The boy was brought to Witmer and studied intensively, using various available psychological laboratory procedures. Many of these procedures, such as the study of reaction time, taken from Wundt's work, have not continued to be used clinically. In any case, on this basis, remedial educational strategies were devised and carried out. These seemed to be helpful. Soon, other individuals were brought to the new clinic, most of them children with problems of academic delay or deviant behavior. As the clinic grew, its staff came to involve PhD students in psychology and a social worker. Also, various physicians were asked to consult on the cases, including a neurologist and an ear, nose, and throat specialist. Witmer presented his ideas for the professional application of psychology to his colleagues at the American Psychological Association (APA) in December, 1896 (Witmer, 1897). Their reaction seemed to be lukewarm at best.

Witmer's graduate students in psychology at the University of Pennsylvania were offered professional training in diverse areas well beyond what might now be considered clinical psychology, branching out to include what is now considered school psychology, speech pathology (Twitmyer & Nathanson, 1932), vocational assessment and guidance (Brotemarkle, 1931), and industrial psychology (Viteles, 1932). His journal, the *Psychological Clinic*, begun in 1907, continued in publication irregularly into the 1930s, for a total of 23 volumes.

It is a historical curiosity that the professional specialty developed by Witmer more closely resembled the modern field of school psychology than what is now thought of as clinical psychology (Fagan, 1996). It is the APA Division of School Psychology, rather than the clinical division, that

has chosen to give an annual Lightner Witmer Award. Witmer worked primarily with children, rather than adults and was more concerned with their academic and cognitive functioning than with their emotional life. He was not much influenced by the French clinical tradition pioneered by Charcot and Janet, and completely rejected the work of Sigmund Freud. Witmer favored educationally oriented interventions rather than psychotherapy or behavior therapy, and the medical procedure he most advocated was the surgical operation of removing a child's adenoids as a way of facilitating normal speech development.

## Alfred Binet

Alfred Binet (1857–1911) was originally trained as a lawyer, and taught himself psychology on the basis of his own reading. He was influenced by individuals such as Ribot, the founder of French psychology, and the famous neurologist Charcot. Binet spent most of his career as an experimental psychologist, and founded an annual psychology journal, the first of its kind in France. In 1905, in response to a request from the ministry of education, Binet and his physician colleague Theodore Simon developed what became known as the first practical "intelligence test" for children (Binet & Simon, 1905). All of its items met the criterion of a demonstrated increase with age in the percent of children passing them, and the test thus enabled the examiner to estimate the child's "mental age" or level of intellectual maturity.

Binet's test materials continued to be used in France informally to gauge children's profiles of cognitive performance in different areas (Schneider, 1992). In English-speaking countries, though, the development and interpretation of the test took some different directions. For example, in Britain, its scores were interpreted in terms of Francis Galton's theory of intelligence as a mostly inherited personal characteristic (Galton, 1892). The concept of a ratio of mental age to chronological age, originating with the German psychologist William Stern (1912), was used to generate an "intelligence quotient" or IQ, although subsequently the ratio IQ was replaced by standard scores based on a comparison of the examinee to others the same age. Even before the development of Binet's test, Charles Spearman (1904) had noted the tendency of scores on cognitive test items to correlate with each other ("positive manifold"), and he interpreted their scores as a measure of general ability or "g," which he hypothesized as a single factor underlying test performance. The American psychologist Henry Goddard had Binet's

test translated into English and validated its ability to diagnose what is now called intellectual disability in children (Zenderland, 1998). Lewis Terman refined and standardized Binet's test in a version that became known as the "Stanford Binet" and provided quantitative norms for it based on a sizable sample of American children (Terman, 1916). Terman's subsequent research followed a group of "gifted" children (with exceptionally high Binet scores) throughout their lives and demonstrated that the test significantly predicted their academic and vocational accomplishments (Terman, 1975).

Soon, the most common activity for practitioners of the newly emerging profession of clinical psychologists in America came to be the administration of individual Binet tests, mostly to children, in clinics, schools, and hospitals. In 1908, the first formal psychology internship program began at the Vineland School, a New Jersey institution for those with intellectual disabilities (Routh, 2000).

## Leta Hollingworth

On December 28, 1917, Leta Hollingworth, J. E. Wallace Wallin, and others founded a new professional organization, the American Association of Clinical Psychologists (AACP) (Routh, 1994). It was the first clinical psychology organization, and a direct ancestor of the present-day Society of Clinical Psychology (Division 12 of the APA). On a global level, clinical psychology shares representation as a division of the International Association of Applied Psychology, founded in 1920. Although Wallin was the president of the AACP in the United States and Hollingworth only the secretary, her name is better remembered today. Hollingworth (1886–1939) suggested in 1918 the possibility of a distinct professional degree for practitioners, which she labeled the PsD, or Doctor of Psychology. This suggestion foreshadowed the PsyD degree, now perhaps the most common type of training for clinical psychologists in the United States, and the DClinPsy degree for clinical psychologists in the United Kingdom, now offered by Oxford University, among other academic institutions. Hollingworth also argued for the legitimacy of clinical psychologists as expert witnesses in court.

The AACP only lasted for 2 years as an organization. In 1919, it was assimilated by the APA as its "Clinical Section," and met annually as part of the APA conventions. For a time, the APA tried to set up a procedure for certifying "consulting psychologists," but this did not work out very well and was soon discontinued. The APA Clinical Section

dissolved itself in 1937, becoming one of the several sections of the new American Association for Applied Psychology. This group continued until 1945, when the AAAP and the APA were consolidated into a new version of the American Psychological Association, which kept the name of the old APA but adopted the structure of the AAAP. The Clinical Section of the AAAP thus became Division 12 of the APA, where it remains today, as the Society of Clinical Psychology. Other national organizations of clinical psychologists, such as that in Britain, mostly did not emerge until after World War II.

Leta Hollingworth is also remembered today as a pioneer advocate of women's rights. In her day, in the early 1900s, most of the clinical psychologists were men, but now most of them are women. A diary kept by Leta's mother reported her father's reaction to her birth in 1886: "I'd give a thousand dollars it if was a boy" (quoted in Klein, 2002, p. 17). Despite this unpromising reception, Leta Stetter was so precocious that she taught herself to read before she entered school. She became a freshman at the University of Nebraska at age 16, and graduated Phi Beta Kappa 4 years later, an occasion for which she was asked to write the class poem. She became a high school teacher and assistant principal. After her marriage to Harry Hollingworth, she moved to New York City, where he entered a PhD program in psychology at Columbia University. Her application for a job as a high school teacher was turned down because the New York City Board of Education had a rule against hiring married women as teachers. She began to take some graduate classes at Columbia, but was turned down for a fellowship because she was a woman. It is thus quite understandable that Leta Hollingworth then became active in the New York Suffrage Party, seeking the vote for women. Harry Hollingworth received his PhD in psychology in 1909, and began teaching at Barnard College, the women's branch of Columbia University. He was hired in 1911 by the Coca Cola Company to carry out research using double-blind procedures on the behavioral effects of caffeine. He hired Leta as assistant director of this project, thus initiating her scientific career in psychology. The funds from the Coca Cola project ultimately allowed Leta to enroll as a graduate student in psychology at Teachers College, Columbia University, where she later studied under Edward L. Thorndike. After receiving her master's degree, she took a part-time job administering Binet tests, an experience that introduced her to clinical psychology. Leta's research in this PhD program showed no relationship between women's menstrual status and their performance on tasks in the psychology laboratory. It also failed to support the hypothesis, then a popular one, that women's intellectual performance is more variable than that of men. After receiving her PhD, she moved on to a career as a professor at Teachers College, Columbia University, where she became a pioneer in the education of gifted schoolchildren (Klein, 2002).

The original rationale for the AACP organization centered on the role of clinical psychologists in administering and interpreting intelligence tests. Once Binet's test was translated into English, it came into wide use in the United States. Wallace Wallin and others argued that this test should only be used by persons who had both academic training in psychology and relevant supervised experience, not by schoolteachers untrained in psychology or by experimental psychologists with no practicum training. The hope was that the new organization would be able to certify and regulate these and other types of "consulting psychologists." The APA attempted for a time to set up such a professional certification procedure, but this did not work. It was not until 1977 that all U.S. states provided statutory licensing for psychologists.

Despite Lightner Witmer's initial emphasis on the importance of intervention and remediation, clinical psychologists during the era before World War II were primarily involved in assessment activities, using not only the Binet and other such intelligence tests, but also in the broader domain of personality. Lewis M. Terman, one of the original members of the AACP and a certified "consulting psychologist," did research further developing the Binet test. He refined and expanded the pool of Binet items, had them administered in a more standardized way, and collected systematic normative data on the performance of children of different ages, producing the "Stanford Binet" test in 1916, which came into common use internationally. Terman initiated important longitudinal research concerning the stability of such test scores and their value in predicting educational, vocational, and other outcomes throughout the lifespan (Terman, 1916, 1975).

## Sigmund Freud

Sigmund Freud (1856–1939) did not originally intend to invent the new discipline he would labeled as "psychoanalysis," but arrived at it by a circuitous route. After a preliminary education including exposure to the Greek and Latin classics, he entered medical school. His goal was an academic career in the field presently called neuroscience. His prospects for

ultimate employment in a university were thwarted, however, in part by Viennese prejudices against Jews. He went into medical practice instead, as a neurologist, so that he could afford to get married (Gay, 1988). To prepare for going into practice, he was awarded a fellowship to go to Paris to study under the most famous neurologist of the time, Jean Charcot. Thus, Freud began to use some of the techniques of hypnotism in treating patients with "hysterical" symptoms, but experience with an early patient led him to discontinue the use of hypnosis. Instead, he had patients "free associate," saying whatever came to mind, and he used the material produced in this way to try to reconstruct the origins of the presenting symptoms. He theorized that such an analysis could alleviate the patient's problems by detecting unconscious material and bringing it to conscious awareness, allowing the patient to cope with it rationally, hence the saying, "where id was, there shall ego be." An important aspect of treatment was the phenomenon of "transference," in which patients became unduly dependent upon their therapists; this was also the subject of the analyst's comments. In 1900, Freud published his famous book on the analysis of dreams as the "royal road to the unconscious" in psychoanalysis, marking the formal announcement of this new discipline.

Freud came to the United States only once, in 1909, at the invitation of psychologist G. Stanley Hall, to speak at the celebration of the 20th anniversary of the founding of Clark University in Worcester, Massachusetts. Although Freud did not particularly like the United States, it proved to be the country in which psychoanalysis achieved its greatest early recognition. The American Psychoanalytic Association was founded in 1911. As the Boston physician Morton Prince said afterward:

> Freudian psychology had flooded the field like a full rising tide and the rest of us were left submerged like clams in the sands at low water.
> (quoted by Hale, 1971, p. 434)

The standard method of educating new psychoanalysts, as it developed during the 1920s, came to consist of three parts: didactic instruction in basic principles, a personal psychoanalysis, and experience carrying out the psychoanalysis of patients under supervision. In Europe, the candidates accepted for such training were not necessarily physicians. In fact, no particular professional prerequisites were enforced, and thus a number of psychologists received psychoanalytic training. The European psychologist Theodore Reik, who worked as a psychoanalyst after

emerging from such training, was taken to court on charges of practicing medicine without a license. Freud, on the witness stand, testified that psychoanalysis was actually a part of psychology rather than of medicine, and thus Reik's use of psychoanalysis with his patients was legitimate. Reik won his case (Freud, 1927). Nevertheless, in 1938, the American Psychoanalytic Association began to enforce the rule that only physicians might be trained for the practice of psychoanalysis. Because Freud was struggling to leave Vienna in 1938 to escape the Nazis and died in London in 1939, he was hardly in any position to intervene personally in this American dispute. The controversial rule was not overturned until 50 years later, in 1988, when the case of *Welch v. American Psychoanalytic Association* (1985) was settled out of court. Now, psychologists may be accepted as candidates for psychoanalytic training in the United States, just as they always had been in other countries. By then, however, the use of psychoanalysis began to wane in the United States.

Before World War II, very few American psychologists worked as psychotherapists, psychoanalytic or otherwise. The same was true of U.S. psychiatrists, whose activities centered on the administration of mental hospitals and the care of psychotic or demented individuals. The war changed all that. For one thing, large numbers of European immigrants, including many psychoanalysts, arrived in the United States, fleeing Hitler. These European analysts formed a cadre for training others in this country. American psychiatrists were able to receive such training through the American Psychoanalytic Association, and psychologists wanting this kind of training were often able to obtain it in irregular ways, including via Theodor Reik's National Psychological Association for Psychoanalysis, in New York.

In addition, the U.S. Armed Forces required many clinicians to deal with the mental health problems that often accompany a war, including what is now labeled post-traumatic stress disorder. Not enough psychiatrists were available to carry out these duties, and thus many doctoral psychologists were brought into mental health–related work. The chief psychiatrist of the U.S. Army during World War II was Brigadier General William C. Menninger, a man strongly identified with psychoanalysis. After the war, the mental health problems of military veterans loomed large. The U.S. Veterans Administration began a massive program of financial support of training in all mental health fields, including psychiatry, psychology, social work, and nursing. The Department of Veterans' Affairs, as it is now known,

is still the largest single employer of clinical psychologists in this country. At the same time, a new federal agency, the National Institute of Mental Health (NIMH) was organized as part of the National Institutes of Health, with responsibilities for supporting both research and training in mental health fields. In response to these federal initiatives, a conference on graduate training in clinical psychology was held in Boulder, Colorado, in 1949. The Boulder Conference (as described by Raimy, 1950) yielded the "scientist-practitioner" model for training clinical psychologists. The recommended curriculum closely followed the model elaborated by psychologist David Shakow, the first chief clinical psychologist at NIMH. Shakow's career was exemplary in its blend of scientific experimental psychology and a psychoanalytic orientation to clinical work. The Boulder Conference formed the basis of a system of graduate programs and internships operating under a new program of accreditation offered by the APA. Many of these new PhD programs in clinical psychology, for example the one at the University of Michigan, incorporated the psychoanalytic training model relatively fully, including didactic instruction, encouragement of personal psychoanalysis, and the supervision of psychotherapy by qualified psychoanalysts.

Meanwhile, clinical psychology was emerging as a discipline in several other countries. After World War II, the United Kingdom, the Scandinavian countries, and others were setting up government-supported national health services (rather than government-supported care for veterans alone). In each of these national health services, clinical psychologists became a mainstay of mental health care, and the psychoanalytic model was as influential in these places as it was in the United States at this time.

Psychoanalysis seems to have reached the peak of its influence in the United States in the mid-1960s. By that time, a large number of the departments of psychiatry in U.S. medical schools had hired psychoanalysts as chairs. After that, Freudian influences in mental health care appeared to wane. One factor in this decline was the reluctance of the psychoanalytic community to subject its treatments to rigorous research concerning their efficacy and effectiveness. A second factor was the cost of treatment, especially of the classical Freudian paradigm, in which patients were seen 5 days a week, sometimes for years on end. Third, by the 1950s, a number of lower-cost, more demonstrably effective pharmacological treatments were emerging for mental health problems, including neuroleptics for managing psychotic behavior,

antidepressants, mood stabilizers, anxiolytics, and others. Finally, alternative psychological treatments began to emerge, including the cognitive and behavioral therapies discussed under the next heading.

### Hans Eysenck

Hans Eysenck (1916–1997) was important to clinical psychology as one of the founders of behavior therapy. The cognitive and behavioral therapies emerged during the latter half of the 20th century as credible alternatives to psychoanalysis. Eysenck was a German who was a firm opponent of the Nazis and soon emigrated to Great Britain. He received his PhD from the University of London, in psychometrics and experimental psychology, under Cyril Burt and was recruited by the prominent psychiatrist Aubrey Lewis to the Institute of Psychiatry at the Maudsley Hospital in London, to start a program in clinical psychology. Eysenck assumed at first that clinical psychologists should occupy themselves only with research and assessment activities, rather than treatment. He was a researcher, himself. In his work, he preferred to collect and analyze data and write articles and books, rather than deal directly with patients as a clinician. In 1949, Eysenck journeyed to the United States (to the University of Pennsylvania), where he began to realize and to agree with the commitment of the post-war generation of clinical psychologists to treatment, and not just assessment (Eysenck, 1949). However, he had no use for the psychoanalytic approaches in which so many of them were interested. He soon scandalized both psychiatrists and psychologists by publishing an article questioning the positive effects of psychotherapy (Eysenck, 1952). In his article, Eysenck described insurance company data that permitted a comparison between the outcomes of persons with neurotic problems who received psychotherapy and others who did not. He pointed out that the success rate of psychotherapy did not exceed the rate of "spontaneous remission" of the patients' difficulties without therapy. Although not a controlled study including random assignment of patients, it did point out the flaw in therapists' previous reasoning that if patients improved after treatment, the treatment must have been responsible.

Eysenck thought that psychological interventions should be based not on Freudian notions, but on ideas compatible with the theories and quantitative, experimental findings of the type of behavioral psychology that was typical of the academic psychology of his day. In his new Department of Psychology at the Institute of Psychiatry, he hired behaviorally

oriented colleagues such as Gwynne Jones and began to train students like Stanley Rachman. Psychiatrist Aubrey Lewis objected to the direction being taken by Eysenck's program, but academic officials at the University of London supported the autonomy of the Psychology Department at the Institute of Psychiatry.

## The Modern Era

What do these developments imply for the status of psychoanalysis? It is clear that Sigmund Freud was a powerful and persuasive writer, and that the cultural influence of his works to this day may be broader than that of any other individual in psychology. Freud's continuing influence within clinical psychology is also considerable. Yet Freud depended largely on the evidence of case histories, never did a psychological experiment, did not make use of quantitative methods, and generally ignored the research literature of nonpsychoanalytic psychology. Many of Freud's medical and psychological colleagues were critical of his approach from the beginning, a fact that is curiously portrayed in histories of psychoanalysis as an example of unconsciously motivated "resistance." Eysenck and his behavioral colleagues simply had the boldness to call the Freudians to account and to engage in much-needed critical thinking about the relevant evidence.

Meanwhile, support for the behavior therapy movement quickly appeared. A behavior modification conference was held in Charlottesville, Virginia, in 1962, and the first behavior therapy journal, *Behaviour Research and Therapy*, began publication in 1963. The interdisciplinary Association for the Advancement of Behavior Therapy first met in 1967, in Washington, D.C., and its name was changed in 2005 to the Association for Behavioral and Cognitive Therapies. Behavioral principles had a profound influence on research and the practice of therapy. In terms of research, pioneering work was carried out by physician Joseph Wolpe of South Africa, described in his 1958 book, *Psychotherapy by Reciprocal Inhibition*. A pioneer in the area of cognitive therapy was psychiatrist Aaron T. Beck (e.g., Beck, 1967). The Skinnerian version of intervention for behavioral problems is known as *applied behavior analysis* and has been particularly valuable in working with persons with intellectual and developmental disabilities, including those with autism (Baer, Wolf, & Risley, 1968).

By the 1980s, the larger scientific community finally began to realize the need for formal randomized clinical trials to evaluate the effectiveness of treatments for psychopathology. Elkin et al. (1989) reported the results of the NIMH Treatment of Depression Collaborative Research Program. Participants in this research were outpatients between the ages of 21 and 60 who met the current Research Diagnostic Criteria for major depressive disorder with specified scores on the Hamilton Depression Rating Scale. Those with other major psychiatric disorders, concurrent psychiatric treatment, or certain medical conditions were excluded, as were actively suicidal individuals. Of 250 potential subjects, 239 entered treatment, of whom 162 completed treatment. They were randomly assigned to either interpersonal psychotherapy, cognitive behavior therapy, imipramine plus clinical management, or pill placebo plus clinical management (medication was administered on a double-blind basis). The psychological treatments were carried out by 13 different therapists, in accordance with detailed treatment manuals. The results showed that the antidepressant medication and the two types of psychological treatment were all significantly more effective than pill placebo but were essentially equivalent to each other in their effects on depression. Critics of such research were quick to point out the additional need for studies on the "effectiveness," not just the "efficacy" of such treatments. In other words, the clinical trials with their formal manuals of procedure were not representative of typical clinical management, and the exclusion conditions made the patients studied also unrepresentative of the broad population of depressed patients. Nevertheless, it is clear that with the NIMH Collaborative Research and similar studies, a new era had arrived. The subsequent emphasis has been on the need for all therapists, when possible, to use "evidence-based" treatments of psychopathology, rather than procedures that have not been tested in a rigorous way. Similarly, the training of all mental health personnel should give priority to teaching treatments that are firmly grounded in the research literature. This is not to deny, however, that clinicians are constantly experiencing variations in the pictures presented by patients' problems, thus requiring a flexible adaptation of established principles.

## Conclusion

This chapter has dealt with a number of strands in the development of Clinical Psychology with a "large C," including its psychoanalytic and cognitive-behavioral aspects. Many psychologists who deliver human services in the United States are specialists in other fields, and are thus are identifiable as clinicians "with a small c," so to speak. Among these

areas are clinical child and adolescent psychology, clinical health psychology, clinical neuropsychology, counseling psychology, rehabilitation psychology, couple and family psychology, clinical geropsychology, school psychology, and in some jurisdictions, clinical psychopharmacology. Early on, in some cases, clinical psychology and school psychology were the same field, but later branched into distinct ones. The history of how each of these special areas developed would require many additional chapters. In many countries in Europe, Latin America, and in many other parts of the world, the patterns of training seen in psychology in the U.S. and the U.K. is not typical. Instead, university psychology graduates receive a diploma or licentiate degree, which is in itself legally sufficient for them to engage in the practice of psychology, although many supplement this by informal training in areas such as psychotherapy. In such countries, master's and doctoral degrees are considered to be preparation for an academic career, not for practice.

My largest effort toward studying the history of clinical psychology is the 1994 book on the history of the organization presently known as the Society of Clinical Psychology, a division of the APA. It was subtitled: "Science, Practice, and Organization," so perhaps these categories will serve in discussing the history of clinical psychology as a larger entity. Clinical psychologists seem to be well accepted as contributors to the scientific study of psychopathology, assessment, and treatment. Their progress in this respect can perhaps be tracked through the volumes of the *Annual Review of Clinical Psychology*, which began publication in 2005.

In terms of practice, doctoral-level clinical psychologists are prominent in the public sector, practicing in Veterans Affairs Hospitals and clinics in the United States and, the in national health services of Great Britain, the nations of the British Commonwealth, and Western Europe. Employment in private-sector mental health is highly competitive in such countries. Psychiatry, once the leading profession in this domain, has lost much of its turf to primary care physicians (and advanced practice nurses), who now write most of the prescriptions for psychotropic medications. Moreover, psychiatry has also lost professional turf to various kinds of nonmedical psychotherapists, including not only doctoral-level psychologists but also master's-level psychologists, social workers, mental health counselors, and many others. Current research does not support the idea that therapists with such different types and levels of professional preparation differ in their effectiveness in treating mental illness. And yet, despite all this professional activity, the mental health needs of the public still do not appear to be very well served. A study by Pratt and Brody (2008) of "depression in the United States household population, 2005–2006," might be taken as a snapshot of the status quo a few years before the beginning of the current world economic recession. A sample of about 5,000 persons representing the adult, civilian, noninstitutionalized U.S. population were given standardized interviews (National Health and Nutrition Examination Survey). Only 29% of those people considered to suffer from depression reported contacting a mental health professional (such as a psychologist, psychiatrist, psychiatric nurse, or clinical social worker) in the past year; of those with severe depression, only 39% reported such contact. Depression is considered a highly treatable condition, yet most people with depression in the United States were not treated. It is clear from such data that clinical psychologists and other mental health professionals have a long way to go to meet their goal of actually helping people even to a minimal extent.

Finally, in terms of organization, clinical psychologists in the United States have been represented by some kind of professional organization since 1917. Similar organizations began to appear in Great Britain, British Commonwealth countries, and in Western Europe, especially after the end of World War II. However, so far, international clinical psychology has not yet gone very far toward dealing with the kaleidoscope of world cultures in existence or achieving any kind of a coherent, organized voice. These remain as issues for the future.

# Emerging Policy Issues for Psychology: A Key to the Future of the Profession

Patrick H. DeLeon, Mary Beth Kenkel, Jill M. Oliveira Gray, *and* Morgan T. Sammons

**Abstract**

Involvement in the public policy process is essential to the continued growth of the profession of psychology. The authors posit that five dimensions of involvement in the policy process are fundamental to ensuring the success of advocacy efforts: patience, persistence, the establishment of effective partnerships, emphasizing interpersonal relationships in the policy process, and the adoption of a long-term perspective. These key mediators are described in the context of current major public policy issues affecting psychology: mental health legislation in general, prescriptive authority, provision of psychological services in community health centers, expansion of the available treatments for autistic spectrum disorders, and recasting psychology as a primary health-care delivery profession. The authors suggest that policy makers will value the contributions of psychology only insofar as they are convinced of the profession's ability to improve the public weal.

**Key Words:** Autism interventions, community health centers, mental health legislation, prescriptive authority, public policy

Those of us who have been personally involved in the public policy process over the years have learned the critical importance of five key mediators of success: patience, persistence, partnerships, personal relationships, and a long-term perspective for the field (DeLeon, in press; DeLeon, Loftis, Ball, & Sullivan, 2006). In this chapter, we provide examples illustrating each of these factors and their contribution to recent policy initiatives affecting psychology. Sometimes one factor, such as the creation of strategic partnerships, is most important in effecting change in public policy. More commonly, however, significant change results from a combination of all these variables.

An immediate example of effective engagement in the public policy process is afforded by large professional advocacy organizations, such as the American Psychological Association (APA). APA has worked over a number of decades to have psychology's voice and expertise heard by those who establish

our nation's domestic and foreign policies, and it can be justly proud of its role in successful passage of landmark legislation, such as the mental health parity bill enacted during the closing hours of the 110th Congress (discussed later). Such success has perhaps been one inspiration for the growing number of psychologists willing to run for elected office at both the local and national level (Sullivan, Groveman, Heldring, DeLeon, & Beauchamp, 1998; Sullivan & Reedy, 2005). Others have been appointed to high-level administrative positions, where they have the ability effectively bring the profession's data-based perspective to addressing society's most pressing needs. In spite of these successes, it remains true that very few, if any, of our current psychology training programs provide the type of "hands-on" exposure to the public policy world necessary to establish the foundation for our next generation of clinicians, educators, and scientists becoming effectively engaged in visionary legislative change (DeLeon, 2002; Kenkel,

DeLeon, Mantell, & Steep, 2005). It is also true that very few of our colleagues appreciate the historical roles that psychologists have had in shaping public policy; for example, that psychologist John Gardner served as Secretary of the then-Department of Health, Education, and Welfare (HEW) during the Great Society era of President Lyndon Johnson and had a major influence on the direction of health-care services. Psychology is a maturing profession, and it is critically important that our field appreciates its own history. Only through that lens we can see both what we have been capable of and the opportunities we have missed. We must find ways to educate current and future psychologists on both this history and in methods of effective engagement. We have no more potent mechanism for the profession to share its expertise for the betterment of society and the advancement of the field.

## Learning About the Public Policy Process

Psychologists and most other health-care providers approach their professional lives from fundamentally different perspectives than do those who establish and implement our nation's health and education policies (DeLeon, Dubanoski, & Oliveira-Berry, 2005). Reflecting upon his year on Capitol Hill, former APA Congressional Science Fellow Neil Kirschner noted that:

> More often than not, research findings in the legislative arena are only valued if consistent with conclusions based upon the more salient political decision factors. Thus, within the legislative setting, research data are not used to drive decision-making decisions, but more frequently are used to support decisions made based upon other factors. As psychologists, we need to be aware of this basic difference between the role of research in science settings and the legislative world. It makes the role of the researcher who wants to put "into play" available research results into a public policy deliberation more complex. Data need to be introduced, explained, or framed in a matter cognizant of the political exigencies. Furthermore, it emphasizes the importance of efforts to educate our legislators on the importance and long-term effectiveness of basing decisions on quality research data . . . . If I've learned anything on the Hill, it is the importance of political advocacy if you desire a change in public policy.
> (*Kirschner*, 2003)

Psychologists involved in the public policy process also must appreciate the structural interrelationships between various congressional committees,

their staffs and the personal interests of Congress-members, and learn to look across federal agencies to systematically explore the range of federal involvement in matters pertaining to the science and profession of psychology. For example, why should the Secretary of the U.S. Department of Agriculture be supportive of investing in programs targeted toward encouraging women to become involved in science, technology, engineering, and math (STEM) initiatives (DeLeon, Eckert, & Wilkins, 2001)? This goal initially seems unrelated to agricultural concerns; however, those familiar with the jurisdiction of the Department of Agriculture would know that it has a broad mission to increase the quality of life for rural America, and historically has done so via funding of educational initiatives through Land Grant institutions. Broadening the focus to include much-needed STEM degrees is a reasonable extension, but it would only be obvious to those familiar with the Department's mission, jurisdiction, and priorities.

Educators, clinicians, and researchers in the field have never operated in a societal vacuum. And yet, very few psychology graduate programs have systematically exposed their students to the rich history of our involvement in such major health-care policy changes such as the community mental health center movement. Few programs have addressed the history and mission of the Centers for Medicare and Medicaid Services (CMS) and how it differs in orientation and programmatic priorities from the Health Resources and Services Administration (HRSA) and the Centers for Disease Control and Prevention (CDC). Very few of psychology's educators are aware of these agencies' different institutional personalities or their institutional affiliations within the Department of Health and Human Services (HHS). Similarly, we would rhetorically ask: How can our graduate students to be expected to appreciate how today's health psychology and integrated-care movements actually rest upon an important public health foundation envisioned by the Minister of National Health and Welfare of Canada in 1974 and President Carter's Surgeon General? (keen readers and students of history may find the answer on page 46)

As a maturing health-care profession, psychology's training programs have an institutional responsibility to educate our next generation regarding the public policy and public health context in which they will someday practice. It is equally important that the next generation of psychologists come to appreciate the public policy implications of the reality that the federal government has a long history of ensuring that those health-care practitioners for

whom it provides training support will be appropriately recognized under each of its health service delivery programs. Perhaps, we would suggest, this vacuum will eventually be filled by psychology's professional schools, which seem to have a broad and global perspective on psychology's future and its potential clinical domain (DeLeon, Kenkel, & Belar, 2007; Kenkel, DeLeon, Albino, & Porter, 2003).

One of the most successful ways for psychologists to learn about the public policy process has been through congressional fellowship programs. The 2008–2009 Fellowship year marked the beginning of the 35th year of the APA Congressional Fellowship Program, with an incoming class of three fellows. APA senior policy advisor Ellen Garrison, also a previous congressional fellow, indicated that a number of psychologists, including herself and Ruby Takanishi (president of the Foundation for Child Development), obtained their Capitol Hill experience under the auspices of the Society for Research in Child Development (SRCD; Ellen Garrison, personal communication, October 23, 2008). A recent APA Fellow and current director of the Fellowship Program, Diane Elmore stated that:

> The APA Congressional Fellowship Program provides psychologists with an invaluable public policy learning experience, contributes to the more effective use of psychological knowledge in government, and broadens awareness about the value of psychology–government interaction among psychologists and within the federal government. As part of the larger Science and Technology Policy Fellowship Program at the American Association for the Advancement of Science (AAAS), APA Congressional Fellows benefit from the distinguished network of organizations dedicated to issues surrounding federal science and technology policy. Since 1974, APA has sponsored 107 Congressional Fellows who have represented the field with excellence and integrity. Participants in the program have gone on to make significant contributions to the field of psychology through clinical practice, research activities, work in the policy arena, and involvement in APA governance.
>
> (*Diane Elmore,* personal communication, October 19, 2008)

Some psychologists have gained a first-hand education in the public policy process by serving as members of Congress. At present, three psychologists are serving in the US Congress, including Rep Tim Murphy of Pennsylvania, Rep Brian Baird of Washington, and Rep Judy Chu of California (Congresswoman Chu also has the distinction of being the first Chinese-American female elected to the US Congress). At the beginning of every session of Congress, the Library of Congress Congressional Research Service develops an in-depth profile of the elected members. Recently, Congress (like the field of psychology) has become increasingly female and more ethnically diverse in its composition. Over the past three Congresses, a record number of women have served, and the 109th Congress also had an unprecedented number of African American members. The average age of the members of both houses is 57—among the oldest of any Congress in history. The overwhelming majority of elected officials have a college education, with 22 members of the House having doctoral degrees, and 13 members of the House and four Senators holding medical degrees. The dominant profession remains law, followed by public service/politics, and business. Of the 540 elected members of the 110th Congress, there were also ten health professionals (Library of Congress, 2008). Ted Strickland, the first psychologist to ever serve in the Congress, has now been elected governor of Ohio; again, being the first psychologist to serve in that capacity. Peter Newbould of the APA Practice Directorate reported that, during the 110th Congress (2007–2008), 14 psychologists were serving in various state House and Senate seats (Newbould, 2007). Given the fundamentally different ways in which members of the health professions and those with law and business professional backgrounds tend to address problems and conceptualize their personal priorities, it is especially important that a significant number of our next generation of psychologists be trained to understand the specific nuances of the legislative process and its highly unique culture, as expressed in its rules, language, and customs, if, as members of society's educated elite, we ever collectively decide to accept our societal responsibility to have a significant role in shaping our nation's priorities (DeLeon, 1986).

In addition to the fellowship program, psychologists and psychologists-in-training also have gained knowledge of the public policy process through advocacy training sponsored by APA and other national and state psychological associations. Each year, during the Educational Leadership Conference sponsored by the Education Directorate and the State Leadership Conference sponsored by the Practice Directorate, participants receive advocacy training and updates on legislative issues relevant to psychologists. They then travel over to Capitol Hill for scheduled appointments with legislators and aides, in order to establish crucial personal connections to better represent the meaning and potential effects of proposed

legislation for society, psychologists, and the people we serve. These psychologists quickly learn that their advocacy efforts are most effective when legislators and staff are shown how proposed legislation will affect real people—clients, students, and the public at large—and how proposed changes will address persisting societal problems. Although research data are useful, a legislator's attention is more fully captured by actual accounts of people who have been helped or could be helped by a new bill or funded program. Psychologists' personal contacts with legislators expand these legislators' knowledge of the critical societal needs by showing them the world that psychologists experience daily—the struggles of individuals and their families, and the impact on individuals and communities from unmet social needs. Psychologists' personal contacts with legislators have been effectively increased through a number of public policy networks affiliated with APA, such as the Federal Educational Advocacy Coordinators (FEDAC) and the Public Policy Advocacy Network (PPAN), through which psychologists are mobilized to contact their legislators at times of important votes.

Although few in number, several academic programs and training councils have begun to highlight the importance of advocacy in their clinical psychology programs (Lating, Barnett, & Horowitz, 2009; Martin, 2006) and provide advocacy experiences for students. By doing so, students learn early on the importance of being involved in the public policy process for the good of their clients and their profession. By observing their professors and clinical supervisors involved in advocacy activities, students learn that advocacy is an important component of their professional roles. They also can become involved in advocacy activities through the APA Graduate Students' (APAGS) Advocacy Coordinating Team (ACT) (see their website, www.apa.org/apags/advocacy/act.html, for more information). Advocacy training materials with important information on the legislative process and effective communication as an advocate are available at the APA website: http://www.apa.org/ppo/ppan/guides.html.

## Patience and Mental Health Parity Legislation

Perhaps one of the most taxing lessons to learn about public policy making is how long it takes to implement significant change, even if highly beneficial. The recently enacted, far-reaching mental health parity legislation (the Paul Wellstone and Pete Domenici Mental Health Parity and Addiction Equity Act of 2008; P.L. 110-343), took over a decade to come to fruition. It was back in April, 1996, when Senator Domenici told his Senate colleagues that "now is the time" to pass legislation requiring insurance companies to cover mental illness just as they did any other medical conditions, yet it took until 2008 for political forces and societal issues to come together to garner broad support for the legislation. Given his daughter's mental health diagnosis, this legislation also provides insight into how "the business of politics can be intensely personal" (Lueck, 2008). APA's senior legislative liaison, Marilyn Richmond, has been working diligently on this critical legislation since 1996, when the initial, albeit limited, federal mental health parity legislation was enacted.

Patience in the public policy process implies a commitment to long-term involvement. Just as psychologists must be lifelong learners to remain effective in their work, so must they have a lifelong presence in public policy processes to have a substantial effect on societal well-being. Patience, however, may be misconstrued as a more passive level of involvement, a "standing on the sidelines" approach. To ensure effective advocacy, patience must be combined with the next important factor—persistence. We illustrate the intersection of these two factors by describing one of psychology's major public policy initiatives of the past two decades: prescriptive authority for appropriately trained practitioners.

## Persistence and Prescriptive Authority
### The Prescriptive Authority (RxP) Agenda

From a public policy perspective, one of the fundamental health-care responsibilities of government is to test out promising and innovative models of health-care delivery, including exploring evolving roles for a range of health-care professionals (e.g., physician assistants and dental extenders). Without question, this has been the case for psychology's prescriptive authority initiative. Psychologists' quest for prescriptive authority vividly demonstrates the value of persistence in the public policy process.

In November 1984, U.S. Senator Daniel K. Inouye urged the membership of the Hawaii Psychological Association (HPA) to seek prescriptive authority (RxP) to improve the availability of comprehensive, quality mental health care. At that time, optometrists were authorized to utilize diagnostic drugs in 39 states (four states allowed therapeutic use), nurse practitioners in 18 states, and the contributions of clinical pharmacists were hardly ever considered (Burns, DeLeon, Chemtob, Welch, & Samuels, 1988; DeLeon, Fox, & Graham, 1991).

In 1991, at the request of the Congress, the Department of Defense (DoD) established a pilot training program at the Walter Reed Army Medical Center, under the auspices of the Uniformed Services University of the Health Sciences (USUHS). In June 1994, then-APA President Bob Resnick attended the graduation ceremonies for the first two DoD prescribing psychologists, including one of the current authors. Over the years, this particular program had been carefully evaluated and demonstrated for both psychology and for our nation's health policy experts that psychologists can be cost-effectively trained to provide high-quality, comprehensive psychopharmacological care (DeLeon, Dunivin, & Newman, 2002; Dunivin & Orabona, 1999; Newman, Phelps, Sammons, Dunivin, & Cullen, 2000). Ultimately, despite ferocious opposition, this program graduated ten prescribing psychologists until political maneuvering by organized medicine eliminated congressional funding in 1997. This program became the model upon which similar training programs in the civilian sector were established.

Notwithstanding objective findings, numerous arguments continue to be marshaled (largely by the psychiatric profession) in the policy process against prescriptive authority for psychologists. These arguments rest mainly on two assertions: that the training of psychologists is insufficient to allow them to provide psychopharmacological services, and that such providers would represent a "public health hazard" who will affirmatively harm their patients. Such arguments represent an extension of the reasoning that the medical profession has traditionally employed when any nonphysician health-care provider group seeks to expand its scope of practice into areas that were previously the exclusive domain of medical doctors: that patients will suffer if care is provided by non–medically trained personnel. This argument, however, has been repeatedly repudiated, as groups as diverse as nurses, podiatrists, dentists, and optometrists have rapidly expanded their professional scopes of practice to procedures including the administration of systemic drugs and surgery (Fox, DeLeon, Newman, Sammons, Dunivin & Baker, 2009; Sammons, 2003).

From an initial Board of Professional Affairs retreat in 1989 and the August 1990 Council of Representatives vote to establish a special task force, the various APA governance elements have intensively deliberated upon all aspects of psychology obtaining prescriptive authority (DeLeon, 2003). In 1995, the APA Council of Representatives voted overwhelmingly to endorse prescriptive authority for

appropriately trained psychologists, as representing APA policy. Today, a number of programs within the civilian sector provide relevant training that meets the APA recommended standards, the majority of which are located within a university-based setting and grant a master's degree upon completion. To date, appropriately 190 post-doctoral graduates have taken the APA Psychopharmacology Examination for Psychologists (PEP exam), which has a passing rate of approximately 71% for first-time test takers (J. Ciuccio, personal communication, October 7, 2008).

The move to acquire prescriptive authority comes in the context of a dramatically altered landscape for all health professions. Optometrists and advance nurse practitioners have acquired prescriptive authority in all states, and clinical pharmacists, under varying conditions, in more than 40 states. Psychology has obtained prescriptive authority in New Mexico (2002) and Louisiana (2004); with Indiana (1993) and Guam (1998) enacting, but not implementing, relevant RxP statutes. Deborah Baker of the APA Practice Directorate reported that, every year, an increasing number of state psychological associations have introduced legislation (Deborah Baker, personal communications, Fall, 2008). In 2007, the Hawaii Psychological Association (HPA) passed such legislation; it was, however, ultimately vetoed by their governor. For 2008, there were a total of eight RxP-related bills, including two sponsored by major labor unions in California. In January 2009, the Hawaii Primary Care Association will sponsor the Hawaii RxP bill and launch their legislative agenda with prescriptive authority for psychologists as one of their top three initiatives. The Florida Psychological Association initiative was modified to become a request for a formal study, with the legislature's Joint Legislative Auditing Committee voting 7–3 to conduct such a study on whether there is a need and/or benefit for granting prescription privileges for psychologists. Historically, 70% of approved proposals from this group eventually become public law. Practice patterns in the jurisdictions that have passed enabling legislation for psychologists suggest that these laws work to expand public health services and do not endanger patients. As of early 2009, 48 medical psychologists have certificates of prescriptive authority in Louisiana. Psychologists have filled positions long left vacant by shortages of psychiatrists, and it is estimated that they have written more than 200,000 prescriptions. The Louisiana State Board of Examiners of Psychologists has not had a single complaint against a medical psychologist in the three years since the

statute was implemented (Glenn Ally, personal communication, October 7, 2008).

The essence of psychology's prescriptive authority agenda rests on the assumption that psychopharmacological service provision from a nonpsychiatric perspective conveys unique benefits. In this "psychological model of pharmacologic service provision" medications are viewed almost always as adjunctive, with the ongoing relationship between therapist and patient assuming primacy. Because psychologists have a wide range of behavioral and psychosocially based interventions in addition to pharmacotherapy, it has also been posited that this integrated approach will lead to better patient outcomes (Sammons, 2001). Former APA Practice Directorate Executive Director and now Provost of Alliant International University Russ Newman predicted: "Prescribing psychologists will use medication in a qualitatively different manner than psychiatrists. They will use pharmacotherapy based on a psychological model of treatment, in contrast to a medical model. The implications of this difference may be profound. The psychological model of treatment can be described as a systems-oriented, holistic, integrative approach…. When other treatments are available, with a psychological model, the power to prescribe is also the power to unprescribe" (Newman, 2000, p. 45).

With persistence, psychologists have been able to gain prescriptive authority through an innovative program in the DoD, as well as in several states. That persistence was fueled by certitude that psychologists would be able to provide more efficacious and needed services with the ability to prescribe. This argument has convinced not only many critics within psychology but also policy-makers seeking to improve mental health services for their constituents. Continued persistence will be necessary to overcome the objections of organized psychiatry and enact prescriptive authority legislation in all the states.

Just as with prescriptive authority, over the past decade, significant progress has been made in ensuring that appropriately trained psychologists throughout the federal system have been able to effectively utilize their clinical skills, whether employed by the DoD, Indian Health Service, U.S. Public Health Service, or Department of Veterans Affairs. Interestingly, it has been our observation that, just as with prescriptive authority, the greatest obstacles this evolution has faced have been within the field of psychology itself; in this case, the institutional reticence on behalf of senior psychologists. Change is always unsettling and frequently takes more time than one might initially

expect (DeLeon, Brown, & Kupchella, 2003). Accordingly, interested students of the public policy process should probably not be surprised or discouraged by how persistent one must be and how long it is taking to fully implement psychology's vision of comprehensive, psychologically based health care (DeLeon, 1988; Kenkel et al., 2005).

## Partnerships and Psychological Service Provision in Community Health Centers
### Enhancing Psychological Service Provision in Community Health Centers

Today's societal problems are complex and multifaceted. Very few can be addressed comprehensively by only one profession, field, or strategy. Yet professional education rarely emphasizes collaborative skills or interdisciplinary approaches. Instead, educational silos exist (O'Neil, 2008) in which professionals become extremely knowledgeable about their own disciplines but have little idea how to talk with, much less work with, others from other professions.

Some psychologist educators, however, such as former Robert Wood Johnson Health Policy Fellow and now Kent State University Provost, Bob Frank, have come to appreciate, undoubtedly through their own personal experiences (i.e., by serving on Capitol Hill), the truly interdisciplinary nature of the public policy process, specifically the health policy process. Dr Frank has been instrumental in establishing health administration and public health training opportunities, so that psychology's graduate students and those of the other health professions have a viable vehicle for being exposed to the nuances and history of our nation's health-care system and the critical need for interdisciplinary cooperation.

More than 25 years ago, there were calls for more cooperation between health and general health providers. It was noted that primary care providers, even then, were charged with providing over 60% of care for those with discernible mental health disorders and that enhanced diagnosis, counseling, better-informed drug prescribing, and referral were key to ensuring high-quality services (Hamburg, Elliott, & Parron, 1982). Those authors also noted that primary care providers required training in discussing mental health issues with patients and called for alternative mechanisms for providing behavioral health-care services in primary care settings. Over 25 years later many of the deficiencies noted by Hamburg, Elliott, and Parron have yet to be addressed and, until recently, there have been few initiatives to promote greater partnerships between

clinical psychologists and primary care providers. There are, however, some encouraging new partnerships, such as those being developed in community health centers (CHCs; DeLeon, Giesting, & Kenkel, 2003). At least four psychology training programs (three in Hawaii; one in Tennessee) are known to provide full-time, and/or, rotations, in pre- and/or post-doctoral training in CHCs (i.e., I Ola Lāhui Rural Hawaii Behavioral Health Training Program, Cherokee Health Systems, Tripler Army Medical Center (TAMC), and Waianae Coast Comprehensive Health Center). All are Association of Psychology Postdoctorate and Internship Centers (APPIC) members, with two being APA accredited (Cherokee Health Systems and TAMC) and one in the process of applying for APA accreditation (I Ola Lāhui). It is possible that this number is an *underestimate* given that other non-APA accredited programs may exist; there may be other CHC-based training programs with APPIC membership only; or, other training programs may have rotations in CHCs but are difficult to locate through existing search lists. In fact, a category specific to CHCs as a program setting is absent from the available list of APA or APPIC programs, which is hopefully something that will change in the near future as more CHC-based psychology training programs evolve.

From a training standpoint, CHCs offer a richness of diversity and complexity of patient populations. Mental health services are offered within the context of primary care, largely to medically underserved individuals. This imbues such sites with the capacity to create culturally competent, innovative, and resourceful psychologists capable of working collaboratively with general health providers and committed to serving the underserved, reducing health disparities, and advocating to reduce stigma and increase psychology's place as a front-line health-care profession (DeLeon, Giesting, & Kenkel, 2003). The challenge is that, at present the training programs that do exist are few and are difficult to develop given the harsh fiscal realities of many state health-care budgets. There is a significant need to establish creative and resourceful means to sustain psychological services and training initiatives in these settings, as well as to continue to develop within APA's framework the support and recognition necessary to expand, sustain, and validate training initiatives within CHCs.

Why should we emphasize the potential of CHCs? These federally qualified community health centers have been in existence serving our nation's most geographically isolated and medically underserved populations for more than 40 years (National Association of Community Health Centers, 2008). Between 1995 and 2004, the numbers of patients served in CHCs increased by more than 50%, from 8.6 to 15 million (Agency for Healthcare Research and Quality Conference Center [AHRQCC], 2005), and the number of uninsured individuals who received care rose from 2.2 to 4 million (DeLeon, Giesting, & Kenkel, 2003). In 2004, the Bureau of Primary Health Care reported that 70.5% of CHC patients were at or below the 100% federal poverty level, 85.3% were uninsured (40.1%) or received some form of public assistance (Medicaid, Medicare), and 63.5% were of a particular ethnic minority group. In addition, as one looks at various states where unique demographics and socioeconomic conditions exist, other medically underserved groups may become more prevalent, such as the homeless, immigrant, and/or migrant populations (Hawaii Primary Care Association, 2006).

Community health centers exist in all 50 states within the United States and are located in high-need communities in order to "provide comprehensive preventive and primary health services to all residents in the service area regardless of [their insurance status or] ability to pay" (AHRQCC, 2005, p. 3). Through this mission, CHCs accomplish impressive tasks to improve access to a range of medical and behavioral health-care services, and reduce health disparities in our nation's most medically underserved populations, including the unmet needs of our rural residents (DeLeon, Wakefield, & Hagglund, 2003). The most common diagnoses seen in CHCs include hypertension, diabetes mellitus, heart disease, asthma, depression, other mood disorders, all mental health, and substance abuse (NACHC, 2005). Approximately 72% and 48% of all health centers provide mental health and substance abuse treatment, respectively. Psychology definitely has multiple roles to play in the administrative, clinical, research, and program development aspects within the CHC model of health-care delivery and should continue to advocate for its role in this clinical setting, in order to provide integrative, whole-person health care for a significant majority of medically underserved populations across the nation.

Initiatives at the national and state levels have reinforced the relevance, benefits, involvement, and sustainability of psychologists in CHCs. The following excerpt, written more than a decade ago, from the Institute of Medicine's "Primary Care: American's Health in a New Era" (1996) speaks to the need for a profession such as psychology to expand beyond

its traditional boundaries and definitions of practice and join with other health-care providers in attempts to improve the status quo of our nation's health-care system:

> Psychiatry itself, in its recent preoccupation with brain biology and psychopharmacology, has evolved in a way that is rather unhelpful to generalists. This is not to minimize the enormous value of this orientation, but to point out the vacuum that it has created. Primary care clinicians have lost a theoretical framework for understanding the human predicament and giving meaning to symptoms. Today, there is no coherent medical psychology that is taught in every medical school. With certain important exceptions, psychiatrists are most often called into service to prescribe or monitor psychotropic drugs or to make difficult diagnostic decisions about seriously disturbed patients. This leaves the primary care clinician without support when she or he is trying to understand and deal with the "ordinary" mental distress, disorders, and illnesses encountered in the daily practice of primary care. (Institute of Medicine, 1996, p. 299)

## PSYCHOLOGISTS IN COMMUNITY HEALTH CENTERS

Psychologists who work in CHCs should be able to provide general, broad-based assessment and treatment services, as well as specialty care in the areas of health psychology, behavioral medicine, and psychopharmacology, in order to function effectively and efficiently (Garcia-Shelton & Vogel, 2002). As in other primary care settings, working in a CHC requires psychologists to possess skill sets that facilitate integrative and collaborative practice within a primary health care team often consisting of medical doctors, nurse practitioners, physician assistants, medical assistants, psychiatrists, social workers, and community outreach workers, as well as administrative, fiscal, and billing staff. A sizable literature on primary care psychology and integrated behavioral health care informs the practice of psychologists who work in CHCs (American Psychological Association, 1998; see special section reviews in Professional Psychology: Research and Practice, 2003, 2005; McDaniel, Belar, Schroeder, Hargrove, & Freeman, 2002; O'Donohue, Byrd, Cummings, & Henderson, 2005; Pruitt, Klapow, Epping-Jordan, & Dresselhaus, 1998; Robinson, 1998). A difference that may be unique to CHCs, however, is the focus on serving medically underserved populations who typically live in rural areas. Community health centers face multiple challenges, including but not

limited to high turnover rates of providers, reduced access to specialty medical care, and patient populations that may be broadly compromised across a variety of health, cultural, and socioeconomic indices. Using Hawaii as an example, the Hawaii Primary Care Association (HPCA, 2006) described their CHC patient profile as: 29% Native Hawaiian, 20% Asian, 25% Caucasian, 14% other Pacific Islander. Fifteen percent of these patients needed interpreters when seeking care, 71% had incomes below federal poverty levels, 74% were rural, 30% were uninsured, and 40% were underinsured (Medicaid or QUEST); 10,700 of these patients were homeless. Anxiety, depression, and adjustment disorders—often in conjunction with domestic violence, substance abuse, homelessness, and chronic diseases—remain among the top mental/behavioral health problems treated. In 2005, the HPCA reported that 70% of Hawaii's CHC patients were in need of behavioral health interventions; however, only 11% actually received these services (demographic and clinical statistics across all 14 CHCs in Hawaii can be found at http://www.hawaiipca.net/chcs). Thus, although the knowledge and skills of psychologists working in primary care apply to CHCs, service planning and practice in such settings brings forth distinct challenges.

Behavioral health program objectives, service delivery, and integration models within Hawaii's CHCs are described in this section. These descriptions reveal that, although foundational elements exist to inform the services provided across CHCs, services provided in each CHC must be adapted to meet specific community needs. A saying made popular among those who have been involved in this expansion work is, "one size fits… only one size." Examples of specific foundational CHC/behavioral health program objectives have included the following: (a) to improve access to medical and behavioral health care, (b) to provide culturally appropriate services and, (c) to reduce health disparities in medically underserved populations. To carry out these objectives, behavioral health service delivery models strive to be evidence-based, accessible, and responsive to community and clinic needs. In most cases, service delivery models evolve over time as a psychologist "works in" to the clinic setting, conducts needs assessments, finds common interests, and builds and eventually assembles the behavioral health service delivery model into the most responsive, relevant, and reliable it can be for that particular CHC.

In general, Hawaiian CHCs have a combined primary behavioral model and colocated specialty

model (Strosahl, 2005), given the "see all comers" and "from cradle to grave" philosophies that comprise CHC patient care. Typically, psychologists have had to begin with the colocated specialty model to initiate behavioral health services in order to generate revenue through traditional third-party reimbursements and then work in a primary behavioral model as CHC resources for behavioral health (namely, to hire more providers or trainees) increase. Ideally, a CHC should have one full-time equivalent (FTE) traditional psychologist and one FTE primary care psychologist per clinic (i.e., Adult, Women's, Pediatrics) within a small to moderate-sized health center (i.e., serving 1,500–3,000 patients per year).

## A Week in the Life of a CHC psychologist

The following is an account of an actual week in the life of psychologists at the Waimanalo Health Center (WHC) in Hawaii (general information about WHC and the Integrated Behavioral Health [IBH] program can be found at http://www.waimanalohealth.com). According to the most recent Uniformed Data Services (UDS, 2008) report, 3,305 total patients were served at WHC (representing a 5% increase from 2007) by medical and behavioral health staff. Medical staff positions include family physicians (2.34 FTE), pediatrician (1.00), nurses (1.50), nurse practitioner (0.04), and other medical personnel (7.16). In addition, there is a nutritionist (0.42 FTE), case manager (1.01), patient community education specialist (0.97), outreach workers (1.51), and eligibility assistance workers (1.01). Of the patients served, 39.7% were male and 60.3% were female (report year January 1, 2008–December 31, 2008). WHC patients by race included, 47% Native Hawaiian, 20% White, 15% other Pacific Islander, 12% Asian, and 6% other. With regard to insurance status, 33% of the WHC patients served in 2008 were uninsured, 43% received Medicaid, 6% received Medicare, and 18% had private commercial insurance. There was a 12% increase in uninsured patients served compared to 2007. The most common medical diagnosis by encounter was for diabetes mellitus, followed by hypertension, asthma, and heart disease. Depression and/or other mood disorders was the primary mental health diagnosis by encounter, followed by anxiety (including post-traumatic stress disorder [PTSD]), and attention deficit-hyperactivity disorder (ADHD). There were 2,121 behavioral health clinical encounters for a total of 338 patients.

In IBH, there are two part-time staff psychologists (.6 FTE each), and one or two practicum students, one or two interns, and one or two post-doctoral fellows at any given point in time. Psychologists are colocated within the health center in a clinic that has a waiting area, an office manager, three individual offices, and one group conference room. This space allows psychologists to see patients for traditional appointments consisting of 30- to 45-minute sessions, while at the same time being steps away from the other primary care clinics (Adult, Women's, Pediatrics) to receive same-day, warm hand-off referrals. In addition, one psychologist or trainee is assigned to the three primary care clinics for 4-hour time blocks, which means that traditional therapy appointments are not made during this time, in order to have a behavioral health provider available to primary care physicians at all times throughout the week. The psychologist or trainee who is scheduled for primary care will not only be the first contact for a warm hand-off referral, but is also present in the primary care clinic to follow-up on all behavioral health screenings (i.e., depression, tobacco use), as well as chronic disease management initiatives that have identified behavioral health as an important part of the patient's care (i.e., diabetes, hypertension).

## Clinical Care

As with any clinical practice, seeing patients is of utmost priority. WHC psychologists strive to see at least eight patients per day to provide general behavioral health service delivery, including traditional individual therapy, group interventions, and child and family interventions for mental health concerns, as well as primary care behavioral health including chronic disease management, smoking cessation, weight management, chronic pain management, psychopharmacology consultation, and medication monitoring. Collaborating and communicating with other primary care providers (namely, physicians, nurses, medical assistants, and outreach workers) happens frequently throughout the day (both in person and through the electronic medical record system) to support patient care in the form of bidirectional referrals, consultations, and following-up regarding important aspects of treatment. On average, primary care providers refer approximately two to four patients to IBH a day. During primary care blocks of time, psychologists

conduct screening for depression and tobacco use, and undertake brief psychological interventions for either mental health or chronic disease management in conjunction with the patient's primary care visit. The screening and intervention focuses on identifying individuals in need who do not ordinarily access behavioral health services, utilizing motivational interviewing strategies to engage them in treatment in a way that circumvents the stigma of mental health services, providing early intervention to prevent the need for more intensive services, and keeping difficult-to-engage/treat individuals in needed behavioral health services until short- and/or long-term treatment goals are met. Depending on the patient's situation, ongoing visits can either occur in primary care exclusively or patients may schedule for follow-up appointments with the psychologist in behavioral health. One of the important benefits of providing this type of primary care intervention is the support it offers to primary care physicians who otherwise have to manage health care for individuals with complex psychosocial issues on their own. In this way, the integrated behavioral health intervention helps not only the patient, but also prevents primary care provider burnout.

**Training and Supervision**

The WHC has established memorandum of agreements with two local training programs, I Ola Lāhui and TAMC. Thus, WHC psychologists engage in both training and supervision of psychology trainees on a daily basis. As stated earlier, there are currently one to three trainees present on any given day, except Fridays. Psychologists share training and supervision responsibilities, and together will provide a total of 5 hours per week of direct supervision. Training often takes place in vivo, as there is not much time to set aside didactic training in addition to direct supervision in the primary care setting. Thus, trainees will observe psychologists conducting therapy with patients as needed, cofacilitating groups, and participating with psychologists in clinic/staff meetings.

Productivity data taken after the first year of I Ola Lāhui trainees alone (6-month, 3-day/week rotation at WHC) indicated services provided to over 274 individuals and families, with 1,080 total patient encounters. On average, patients attended an average of 3.9 sessions with trainees across all ethnic groups. Interestingly, although the research literature in this area would suggest that ethnic minority group members have higher attrition from behavioral health services, Native Hawaiian patients using these behavioral health services stayed for an average of 4.2 sessions. Trainees have also been well received by the WHC administration and clinical staff, who greatly value the work they perform and have been very supportive of continuing this training component for the past 8 years.

**Clinical Research**

Blocks of time are not scheduled for research only. However, because psychologists are invested in program development and evaluation, they do gather and track patient outcome data on a regular basis. These data are used both to inform clinical practice and to describe IBH productivity and patient outcomes.

**Administration**

Psychologists attend monthly staff meetings, provider meetings, provider huddles, and clinic huddles, which are all interdisciplinary and designed to enable discussions among providers and administrative staff regarding multiple topics, including clinic operations (i.e., policy and procedures), program development initiatives, health center updates, financial reports, quality improvement/quality assurance, and general announcements.

Thus, psychologists at WHC spend the majority of their week engaged in clinical patient care, 50% of which takes place within the primary care clinics, mainly Adult Medicine and Women's Health. To maximize work volume and maintain a workforce development training capacity, psychologists also supervise psychology trainees from two local psychology training programs on a weekly basis (totaling 4 days/week). Administrative responsibilities also assume dedicated blocks of time whereby psychologists engage with other health-center staff and providers to support daily center operations, as well as facilitate positive and productive working relationships. Finally, program development and evaluation is the type of research that characterizes this aspect of professional practice in the life of a CHC psychologist.

### Hawaii CHC Initiatives

In the late 1990s, Hawaii's community health-care leaders and psychologists from the TAMC Department of Psychology, convened to discuss innovative ways that would combine federal and state resources to enable greater health-care access for Native Hawaiians in rural communities (Oliveira, Austin, Miyamoto, Kaholokula, Yano, & Lunasco, 2006). Native Hawaiians continue to suffer significant health disparities compared to other ethnic groups in Hawaii, largely due to risk factors that include acculturative stress and access to care challenges (Blaisdell, 1993; Braun, Yee, Browne, Mokuau, 2004; Hope & Hope, 2003; Johnson, Oyama, LeMarchand, & Wilkens, 2004). Native Hawaiians have high prevalence rates of certain chronic diseases such as obesity, diabetes, and cardiovascular disease; higher health risk behaviors such as tobacco and/or illicit drug use; and are overrepresented in the under- and uninsured, poverty, and homelessness groups, as well as in rural, medically underserved areas (Banks, Buki, Gallardo, & Yee, 2007; Oliveira et al., 2006). In 2000, the civilian post-doctoral psychology training program began at TAMC with the express interest of increasing access to culturally appropriate behavioral health care for Native Hawaiians in rural, medically underserved areas in order to enhance the existing health-care system and reduce significant health-care disparities that have plagued the indigenous population of Hawaii for decades (Hope & Hope, 2003).

Partnerships established between TAMC, Hawaii's CHCs, and Native Hawaiian Health Care System clinics (NHHCS) have led to successful outcomes from both service delivery and training perspectives. In terms of service delivery, psychologists have either started or expanded existing behavioral health services in 11 of the 14 CHCs and in one of the five NHHCS clinics. In 2009, 12 psychologists were employed in either a part- or full-time basis, and 13 psychologists in training were present. The TAMC training model was instrumental in the development of two additional full-time training programs in medically underserved communities via colocation and integration within CHCs and NHHCS: I Ola Lāhui Rural Hawaii Behavioral Health Program, and the Waianae Coast Comprehensive Health Center Psychology Training Program. Both programs are members of APPIC in good standing; the former also seeks APA accreditation and is currently in the accreditation process. One of the current authors is a faculty member of the I Ola Lāhui Rural Hawaii Behavioral Health Program and will thus further describe this training program to highlight an example of a nontraditional psychology training program that aims to be part of the systematic change necessary to address pressing cultural, economic, societal, and political issues that impact our nation's poorest and most vulnerable populations.

### I Ola Lāhui Rural Hawaii Behavioral Health Program

I Ola Lāhui is a Hawaiian phrase that means, "So that the people will live and thrive." I Ola Lāhui is a clinical psychology training program whose mission is to provide culturally minded evidence-based behavioral health care that is responsive to the needs of medically underserved and predominantly Native Hawaiian rural communities. In recognition of Hawaii's urgent need for more quality behavioral/mental health care, I Ola Lāhui is committed not only to providing services but also to evaluating the effectiveness of the services provided and training future providers, with the hope of making a substantial contribution to the health and well-being of our *Lāhui* (people). I Ola Lāhui was incorporated in June 2007, and received its nonprofit 501(c)3 designation status on July 11, 2007. During the first year of internship training, I Ola Lāhui participated as a site in the APA accredited Argosy University/Honolulu Internship Consortium, and applied for its own APPIC membership in 2007. Official membership status was granted on November 27, 2007. Intake of the first cohort of interns as an independent training site occurred in June 2008 for the 2008–2009 training year. I Ola Lāhui sees the vital importance of offering training experiences for future psychologists that incorporate the domains expressed in this chapter, such as advocacy and public policy, interdisciplinary/primary care psychology, integrated behavioral health care, and prescriptive authority for psychologists. I Ola Lāhui is nontraditional in that it serves as both administrative and training functions, without being housed within a larger institutional setting, It is among the first of its kind to take psychology training beyond the proverbial four walls in order to answer the societal call to improve health provider shortages, access issues, and health disparities.

## Personal Relationships
### Advocating for Effective Treatment: Autistic Spectrum Disorders

Building personal relationships is critically important in the public policy process. This includes forming relationships with legislators and their staff,

with directors and staff at federal and state agencies, with professionals with related goals, and with individuals who are looking for solutions to pressing problems. This skill should be easily acquired by clinical psychologists who are experts at building rapport, empathic listening, and establishing bonds with others.

What is the value of these relationships? First, they allow psychologists to learn about issues that are of concern to planners and recipients of health-care services. The psychologist has the opportunity to broaden a legislator's (who may have a personal interest, such as a family member or constituent struggling with mental illness) understanding of the issue and its impact on the people the legislator is trying to serve. The personal relationships also allow the psychologist to join in proposing and working on solutions on a more informal basis. Early involvement in the problem solution helps to ensure the consideration of factors important to psychology, such as the impact of proposed legislation/programs on different minority or disenfranchised groups. Personal contacts also allow the psychologist to gain credibility as a professional with information and expertise in areas of concern and one interested in assisting in the complex, rough-and-tumble, and sometimes frustrating process of public policy. Over time, through these personal contacts, psychologists can become known as reliable and informative advisors; as they acquire referent authority, they can have more influence when there are particular issues for which psychologists are advocating.

A network of personal relationships and professional contacts is key to getting things done, particularly in major initiatives involving large-scale shifts in policy or large budgets. This became exceedingly evident to one of the authors as she developed a center to provide autism services and research. Autism spectrum disorders (ASD) are neurodevelopmental disorders commonly diagnosed before the age of 3, now estimated to affect one in 110 children in the United States (Centers for Disease Control [CDC], 2009). The major characteristics of ASDs are impaired social and language skills and a restricted repertoire of activities and interests. In addition, many individuals with autism have mental retardation and may exhibit self-injurious, stereotypical, and/or aggressive behaviors. Because of the recent exceedingly rapid increase in the incidence of autism (CDC, 2007) many families, schools, health facilities, and social service agencies are increasingly overwhelmed by the treatment needs of this population. In general, such agencies have few resources to provide the intensive behavioral treatments and other interventions that have been shown to be the most efficacious with the disorder.

Clearly a need existed, and with a doctoral program in clinical psychology and a large master's program in applied behavior analysis (ABA), the School of Psychology at Florida Institute of Technology had a wealth of faculty and student resources that could be utilized to address significant needs of individuals with ASDs and those who care for them. It took an assemblage of many people working together—many with long-term personal relationships—to establish a center that would bring these resources to affected families. These included a trustee of the university and his wife, who had encountered the struggles of finding treatment for their son with ASD and who provided major funding for the center; the district's congressman, a physician committed to helping children with ASD who was made aware of the university's capabilities in this area and worked to secure Health Resources Services Administration (HRSA) funding for the center; a dedicated community advisory group, made up of parents and professionals caring for children with ASD, who helped develop the mission and vision of the center and build community awareness and support; school teachers, administrators, and other health-care professionals who flocked to training programs given by the center and provided vocal support for its establishment; and local media, who assisted the center in bringing information about autism to their readers/audiences and described the center as a valuable community asset.

With key input from the community it aimed to serve, the center developed a mission that was broader than it might have been if developed only by the university's school of psychology. There was a call for a "one-stop" center, which would include multidisciplinary services and a seamless transition among services—attributes that the public also are calling for in their general health-care settings.

The center has the benefit of being a major treatment center under the direction and control of a psychology program, with a priority on providing behavioral and psychological services, as opposed to more typically encountered programs housed in medical settings. This provides high visibility to the field of psychology as the primary profession for autism treatment, training, and applied research. This type of self-determinism is a hallmark of professions (Abbott, 1988; Larson, 1977) and is growing evidence of psychology's rising prominence as a "health" profession.

The center provides training to clinical psychology and behavior analysis students, and by doing so hopes to address the significant manpower shortage of professionals able to deliver autism services. The center also allows complete control of the training experiences provided to the students. This permits rapid adoption of new evidence-based treatment methods and the capability of developing and evaluating new programs to deal with this complex disorder.

Ongoing operation of the center requires a sustainable funding source. With this in mind, the school has been involved in recent legislative initiatives to require private insurance companies pay for autism services, specifically ABA interventions. With the strong backing of the advocacy group, *Autism Speaks*, by May 2010, these efforts have been successful in 19 states, including Florida (Autism Speaks, 2010). Through these advocacy efforts, stable funding is available not only for the Center but also for the services that the graduates of the school will provide in the future.

The autism center is an example of how psychology can be involved in multiple ways in the public policy process. A pressing societal need was identified; psychological resources were available and willing to be used to address it; a workable proposal was developed by the university and those affected by autism; contact with legislators informed them of the problem and possible solutions; community support was gathered and used to secure private and federal funding; partnerships with like-minded groups increased advocacy for support for autism services; and state and federal initiatives were obtained to develop and sustain the center. The network of personal relationships among the people involved in the center's development was critical to garnering support and action. It also required persistence and passion—and the next factor to be discussed: a long-term perspective for developing the center.

## Long-term Perspectives: Moving Toward a Primary Health-care Profession

As previously stated, effective involvement in the policy process requires a long-term perspective. The profession must determine its long-term goals and plan and carry out the strategies to reach them. What is clinical psychology's long-term goal? There probably is no single answer that would be unanimously adopted by all in the field, but certain elements of a future vision would probably be agreed upon by many: being recognized as the most qualified behavioral health provider, having the resources to conduct psychological research and implement

psychological services, and inclusion as essential professionals in the solution of society's pressing problems. The more unified clinical psychology can be in the delineation of these long-term goals, the more effective the profession will be as a partner in the policy process.

We offer this long-term goal: that psychology be recognized as a front-line, primary health profession (DeLeon, Brown, & Kupchella, 2003). Such a perspective indicates that psychology be recognized as contributing not only to better mental health care, but also to better general health care, and it would be seen as an essential resource in efforts to improve healthy functioning. This perspective is not new, but has yet to be fully integrated into public policy.

Over 35 years ago, the government of Canada recognized the importance of good health for quality of life and the value of a broadened conceptualization of health care:

> Good health is the bedrock on which social progress is built. A nation of healthy people can do those things that make life worthwhile, and as the level of health increases so does the potential for happiness. The Governments of the Provinces and of Canada have long recognized that good physical and mental health are necessary for the quality of life to which everyone aspires. Accordingly, they have developed a health care system which, though short of perfection, is the equal of any in the world. For these environmental and behavioural threats to health, the organized health care system can do little more than serve as a catchment net for the victims. Physicians, surgeons, nurses and hospitals together spend much of their time in treating ills caused by adverse environmental factors and behavioural risks. . . . It is therefore necessary for Canadians themselves to be concerned with the gravity of environmental and behavioural risks before any real progress can be made. . . . The Government of Canada now intends to give human biology, the environment, and lifestyle as much attention as it has to the financing of the health care organization so that all four avenues to improved health are pursued with equal vigour. Its goal will continue to be not only to add years to our life but life to our years, so that all can enjoy the opportunities offered by increased economic and social justice. (*Lalonde*, 1974, pp. 5-6).

Similar sentiments were expressed a few years later by the U.S. government:

> (L)et us make no mistake about the significance of this document. It represents an emerging

consensus among scientists and the health community that the Nation's health strategy must be dramatically recast to emphasize the prevention of disease… . But we are a long, long way from the kind of national commitment to good personal health habits that will be necessary to change drastically the statistics about chronic disease in America… . (U.S. Dept. of Health, Education, and Welfare [HEW], 1979, pp. vii, ix).

Prevention is an idea whose time has come. We have the scientific knowledge to begin to formulate recommendations for improved health… . (O)f the ten leading causes of death in the United States, at least seven could be substantially reduced if persons at risk improved just five habits: diet, smoking, lack of exercise, alcohol abuse, and use of antihypertensive medication… . (A)lthough people can take many actions to reduce risk of disease and injury through changes in personal behavior, the health consequences are seldom visible in the short run… . To imply, therefore, that personal behavior choices are entirely within the power of the individual is misleading… . (HEW, 1979, pp. 7, 14, 18).

Beginning in early childhood and throughout life, each of us makes decisions affecting our health. They are made, for the most part, without regard to, or contact with, the health care system. Yet their cumulative impact has a greater effect on the length and quality of life than all the efforts of medical care combined (*HEW,* 1979, p. 119).

Challenge To The Nation. Americans are becoming healthier people—but more can be achieved. This report has described and documented the potential for better health at each stage of life. It has set forth specific goals to be attained over the next decade, and a full agenda of possible actions to be taken. To reach these goals will require a national effort and the commitment of people extending far beyond what we traditionally consider the health sector. No single segment of society can accomplish them alone. Unnecessary death and disability can be prevented— and better health can be maintained—only through a partnership that involves the serious commitment of individual citizens, the communities in which they live, the employers for whom they work, voluntary agencies, and health professionals. Government agencies at all levels must encourage and bolster their efforts. How to move expeditiously toward the goals of prevention is the challenge for the years to come (*HEW*, 1979, p. 141).

The Institute of Medicine (IOM) was established in 1970 by the National Academy of Sciences to enlist distinguished members of the appropriate professions in the examination of policy matters pertaining to the health of the public. Acting as a health policy advisor to the federal government, it has recently issued a series of reports calling for major and unprecedented changes in both the structure and focus of our nation's health-care system.

The heaviest burdens of illness in the United States today are related to aspects of individual behavior, especially long-term patterns of behavior often referred to as 'lifestyle.' As much as 50% of mortality from the ten leading causes of death in the United States can be traced to lifestyle. Regardless of the health-risky behavior or the disease, treatment and prevention should be major research issues for the biobehavioral sciences. Attention is being given to methods of altering the burden of illness by changing behavior. This requires first that changes in behavior can be shown to result in improved health and second that effective methods be found to help large numbers of people to make such changes. Much remains to be learned, but the existing research base provides strong evidence that the biobehavioral sciences can make substantial and unique contributions to dealing with much of the disease that now constitutes the main burden of illness in this country. (*Hamburg et al.* 1982, p.p. 3,16).

Psychology appears ready to respond to this broadened perspective on health care, as reflected in these statements by former APA President Ron Levant, formerly Dean of the Buchtel College of Arts and Sciences at the University of Akron:

Mind-Body dualism, is, in a word, bankrupt. We need to transform our biomedical health care system to one based on the biopsychosocial model, which will emphasize *collaboration* between medical and behavioral healthcare providers, and the *integration* of psychology into the very heart of health care. In order to reform the U.S. health-care system along these lines we must appeal directly to the public and to decision-makers, not alone, but in collaboration with other like-minded physician, provider, consumer, and policy groups. We need to articulate the public's dissatisfaction with the biomedical health-care system that results in their care provider not having time to listen to all of their concerns or offering what amounts to limited care. We need to put forth a vision of integrated care, a care system

that offers Health Care for the Whole Person. This was the second of my initiatives as President of APA. It is one very concrete example of how psychology can address urgent public needs and make psychology a household word.

(*Levant*, 2006, pp. 387–388).

The 21st century will be an era of educated consumers utilizing the most up-to-date technology to ensure that they and their loved ones will have timely access to data-based, objective standards of care, provided by technology-literate, interdisciplinary-oriented health-care providers. A recent report from the IOM concluded that not only is the health-care system in its current configuration incapable of engaging in effective future planning, inasmuch as we devote most of our energy toward the management, not the prevention of chronic disease. The lack of integration across provider groups and delivery settings was also seen as a significant impediment in the development of effective and economical health-care systems. The IOM saw behavioral interventions regarding diet, exercise, and substance abuse as key in a new mindset of prevention. Interdisciplinary coordination, using providers skilled in the latest in medical informatics to efficiently share information, track interventions and outcomes, and manage costs was also seen as essential (IOM, 2003a, 2003b).

Each year, more than 33 million Americans use health-care services for their mental health problems or conditions resulting from their use of alcohol, inappropriate use of prescription medications, or, less often, illegal drugs. In 2006, *Improving the Quality of Health Care for Mental and Substance-Use Conditions: Quality Chasm Series* was released, in which the IOM concluded that their Quality Chasm framework is, in fact, applicable to health care for mental and substance-use conditions. This newest report noted that these conditions are the leading cause of combined disability and death for women and the second highest for men. "Effective treatments exist and continually improve. However, as with general health care, deficiencies in care delivery prevent many from receiving appropriate treatments. That situation has serious consequences—for people who have the conditions; for their loved ones; for the workplace; for the education, welfare, and justice systems; and for our nation as a whole" (IOM, 2006, p. 1). Five psychologists served on the committee issuing this report, and the assistance of Jalie Tucker, then-Chair of the APA Board of Professional Affairs, was expressly noted.

Supporting this perspective, the President of the IOM declared: "As the Committee has concluded, improving our nation's general health, and the quality problems of our general health care system, depends upon equally attending to the quality problems in health care for mental and substance-use conditions…. Dealing equally with health care for mental, substance-use, and general health conditions requires a fundamental change in how we as a society and health-care system think about and respond to these problems and illnesses. Mental and substance-use problems and illnesses should not be viewed as separate from and unrelated to overall health and general health care. Building on this integrated concept, this report offers valuable guidance on how all can help to achieve higher-quality health care for people with mental or substance-use problems and illnesses. To this end, the Institute of Medicine will itself seek to incorporate attention to issues in health care for mental and substance-use problems and illnesses into its program of general health studies" (IOM, 2006, p. x).

Becoming front-line primary health professionals is our long-term perspective for the field. As just seen, voices from outside the profession are articulating the same need for such a front-line behavioral health professional. The time seems ripe for taking strides to achieve this vision. Many opportunities will exist for doing so as a new administration undertakes long-overdue structural changes in the American health-care system. Psychology must forcefully articulate its vital role in health care and what it can do to meet the current and future health-care challenges of the populace. Only by doing so can the profession be seen as an integral component of a new health-care delivery system.

## Conclusion

The challenge for psychology's training and service delivery leaders in the 21st century will be designing clinical initiatives and training opportunities that are responsive to the unprecedented challenges that society at large will be facing. To do so effectively, psychologists must become more involved in the public policy process. As we have suggested, an important element of this role will be to ensure that those who establish our nation's health and educational policies become intimately aware of psychology's potential contributions to their underlying mission. Over the years, there have always been a number of specific legislative and administrative initiatives (e.g., inclusion in the Department of Defense CHAMPUS and later TRICARE reimbursement

programs, the ability to bill under Medicare [most recently the expanded ability to bill for Evaluation and Management codes], Graduate Medical Education, and the federal Criminal Justice program) of definite and concrete interest to professional psychology. In addition to focusing on these specific programs, we would suggest that even more important in the long run for every health-care profession is building an institutional appreciation and capacity for understanding how government leaders (and increasingly those of the private sector) systematically seek to address society's most pressing needs. Such knowledge reveals past strategies and indicates how new initiatives could be designed. Participation in this decision-making process requires proactive leadership on the part of psychologists. And what better way to learn where proactive leadership is necessary than by studying the lessons of the past from our public health colleagues (DeLeon & Pallak, 1982)?

Clinical psychology can have a larger and stronger influence on public policy if such a role is embraced by the profession. As we have illustrated in this chapter, it will require patience while being persistent, forging partnerships and building personal relationships, and most importantly maintaining the long-term perspective of what clinical psychology can be and can contribute to society. It is a long-term commitment. The time to renew that commitment is now.

# Research Methods in Clinical Psychology

Philip C. Kendall *and* Jonathan S. Comer

**Abstract**

This chapter describes methodological and design considerations central to the scientific evaluation of treatment efficacy and effectiveness. Matters of design, procedure, measurement, data analysis, and reporting are examined and discussed. The authors consider key concepts of controlled comparisons, random assignment, the use of treatment manuals, integrity and adherence checks, sample and setting selection, treatment transportability, handling missing data, assessing clinical significance, identifying mechanisms of change, and consolidated standards for communicating study findings to the scientific community. Examples from the treatment outcome literature are offered, and guidelines are suggested for conducting treatment evaluations that maximize both scientific rigor and clinical relevance.

**Key Words:** Measurement, random assignment, randomized clinical trial (RCT), treatment evaluation, treatment outcome

Central to research in clinical psychology is the evaluation of treatment outcomes. Research evaluations of the efficacy and effectiveness of therapeutic interventions have evolved from single-subject case histories to complex multimethod experimental investigations of carefully defined treatments applied to genuine clinical samples. The evolution is to be applauded.

In this chapter, we focus on how best to arrange these latter complex evaluations in a manner that maximizes both scientific rigor and clinical relevance. Although all of the ideals are rarely achieved in a single study, our discussions provide exemplars nonetheless. We encourage consistent attempts to incorporate these ideals into research designs, although we recognize that ethical and logistical constraints may compromise components of methodological rigor. We organize our chapter around the things that matter: (a) matters of design, (b) matters of procedure, (c) matters of measurement, (d) matters of data analysis, and (e) matters of reporting.

## Matters of Design

To adequately assess the causal impact of a therapeutic intervention, clinical researchers use control procedures derived from experimental science. The objective is to separate the effects of the intervention from changes that result from other factors, which may include the passage of time, patient expectancies of change, therapist attention, repeated assessments, and simply regression to the mean. These extraneous factors must be "controlled" in order to have confidence that the intervention (i.e., the experimental manipulation) is responsible for any observed changes. To elaborate, we turn our attention to the selection of control conditions, random assignment, evaluation of response across time, and comparison of multiple treatments.

### Selecting Control Condition(s)

Comparisons of persons randomly assigned to different treatment conditions are required to control for factors other than the treatment. In a "controlled"

treatment evaluation, comparable persons are randomly placed into either the treatment condition (composed of those who receive the intervention) or the control condition (composed of those who do not receive the intervention), and by comparing the changes evidenced by the members of both conditions the efficacy of therapy over and above the outcome produced by extraneous factor (e.g., passage of time) can be determined. However, deciding the nature of the control condition (e.g., no-treatment, wait list, attention-placebo, standard treatment-as-usual) is not simple (see Table 4.1 for recent examples).

When comparison clients are assigned to a *no-treatment* control condition, they are administered the assessments on repeated occasions, separated by an interval of time equal in length to the therapy provided to those in the treatment condition. Any changes seen in the treated clients are compared to changes seen in the nontreated clients. When treated clients evidence significant improvements over non-treated clients, the treatment is credited with producing the changes. This no-treatment procedure eliminates several rival hypotheses (e.g., maturation, spontaneous remission, historical effects, regression to the mean). However, a no-treatment control condition does not guard against other potentially confounding factors, including client anticipation of treatment, client expectancy for change, and the act of seeing a therapist—independent of what specific

**Table 4.1 Types of control conditions in treatment outcome research**

| Control condition | Definition | Recent example in literature | |
| --- | --- | --- | --- |
| | | Description | Reference |
| No-treatment control | Control clients are administered assessments on repeated occasions, separated by an interval of time equal to the length of treatment. | Refugees in Uganda diagnosed with PTSD were randomly assigned to active trauma-focused treatments or a control condition. Individuals in the control condition received no treatment but were assessed on repeated occasions. | Neuner et al. (2008) |
| Waitlist control | Control clients are assessed before and after a designated duration of time, but receive the treatment following the waiting period. They may anticipate change due to therapy. | Anxious children and their parents were randomly assigned to group treatment, bibliotherapy, or a 12-week waitlist control condition. | Rapee et al. (2006) |
| Attention-placebo/ nonspecific control | Control clients receive a treatment that involves nonspecific factors (e.g., attention, contact with a therapist) | Children with anxiety disorders were randomly assigned to cognitive-behavioral treatments or a control condition in which they received weekly attention and psychoeducation. | Kendall et al. (2008) |
| Standard treatment/routine care control | Control clients receive an intervention that is the current practice for treatment of the problem under study. | Families were randomly assigned to either a parent-management training or a regular services comparison group. | Ogden & Hagen (2008) |

treatment the therapist actually provided. Although a no-treatment control condition is sometimes useful in the earlier stages of evaluating a treatment, other control procedures are preferred.

Utilizing a *waitlist condition*—a variant of the no-treatment condition—provides some additional control. Clients in the waitlist condition expect that after a specified period of time they will be receiving treatment, and accordingly may anticipate changes due to this treatment, which may in turn affect the course of their symptoms. The changes that occur for wait-listed clients are evaluated at regular intervals, as are those of the clients who received therapy. If we assume the clients in the waitlist and treatment conditions are comparable (e.g., gender, age, ethnicity, severity of presenting problem, and motivation), then we can make inferences that the changes in the treated clients over and above those also manifested by the waitlist clients are likely due to the intervention rather than to any extraneous factors that were operative for both the treated and the waitlist conditions (e.g., expectations of change). The important demographic data are gathered so that statistical comparisons can be conducted to determine condition comparability. Waitlist conditions, like no-treatment conditions, are of less value for treatments that have already been examined versus somewhat "inactive" comparisons.

There are potential limitations associated with waitlist controls. First, a waitlist client might experience a life crisis that requires immediate professional attention. For ethical purposes, the status of control clients should be monitored to ensure that they are safely able to tolerate the treatment delay. In the event of an emergency, the provision of professional services will compromise the integrity of the waitlist condition. Second, it is preferable that the duration of the control condition be the same as the duration of the treatment condition(s). Comparable durations help to ensure that any differential changes between the conditions would not be due to the differential passage of time. However, suppose an 18-session treatment takes 4–5 months to provide— is it ethical to withhold treatment for 4–5 months as a wait period (see Bersoff & Bersoff, 1999)? With long waitlist durations, the probability of differential attrition arises, a situation that could have a compromising effect on study results. If rates of attrition from a waitlist condition are high, the sample in the control condition may be sufficiently different from the sample in the treatment condition, and no longer representative of the larger group (e.g., the smaller waitlist group at the end of the study now only represents clients who could tolerate and withstand a prolonged period without treatment).

No-treatment or waitlist controls provide initial evidence of treatment efficacy but are less important once a treatment has, in several evaluations, been found to be more effective than "inactive" control conditions. *Attention-placebo* (or nonspecific treatment) control conditions are an alternative to the waitlist control that rule out some threats to internal validity, and control for the effects that might be due simply to meeting with and getting the attention of a therapist. In addition, these participants receive a description of a treatment rationale (an explanation of the treatment procedures offered at the beginning of the intervention). The rationale provided to attention-placebo clients mobilizes an *expectancy* of positive gains. (For discussion of treatment elements separate from the proposed active components see Hollon & DeRubeis, 1981; Jacobson & Hollon, 1996a, 1996b).

Attention-placebo conditions enable clinical researchers to identify the changes produced by specific therapeutic strategies over and above nonspecific strategies. For example, in a recent randomized clinical trial (RCT) (Kendall et al., 2008), children with anxiety disorders received cognitive-behavioral treatment (CBT; either individual or family CBT) or a manualized family education, support, and attention (i.e., FESA) condition. Individual and family-based CBT was found to be superior to FESA in reducing the children's principal anxiety disorder. Given the nature of the FESA condition one was able to infer that the gains associated with receiving CBT are not likely attributed to "common therapy factors" such as learning about anxiety/emotions, experience with an understanding therapist, attention to and opportunities to discuss anxiety.

Despite the advantages of attention-placebo controls, they are not without limitations (Parloff, 1986). Attention placebos must be devoid of therapeutic techniques hypothesized to be effective, while at the same time instilling positive expectations in clients and providing professional contact. To offer such an intervention in the guise of effective therapy is acceptable when clients are fully informed in advance and sign informed consent forms acknowledging their willingness to take a chance on receiving either a psychosocial placebo condition. Even then, an attention-placebo condition may be difficult for the therapist to accomplish.

Methodologically, it is difficult to ensure that therapists who conduct attention-placebo conditions have the same degree of positive expectancy for client gains as do therapists conducting specific interventions (Kendall, Holmbeck, & Verduin, 2002; O'Leary & Borkovec, 1978). "Demand characteristics" would suggest that when therapists predict a favorable outcome, clients will tend to improve accordingly (Kazdin, 2003). Thus, therapist expectancies may not be equal for active and placebo conditions, reducing the interpretability of the findings. Similarly, clients in an attention-placebo condition may have high expectations at the start, but may grow disenchanted when no specific changes are emerging. If study results suggest that a therapy condition evidenced significantly better outcomes than a attention-placebo control condition, it is important that the researcher evaluate clients' perceptions of the credibility of the treatment and their expectations for change to confirm that clients in the attention-placebo condition perceived the treatment to be credible and expected to improve.

The use of a *standard treatment* (treatment-as-usual) as a comparison condition allows the researcher to evaluate an experimental treatment relative to the intervention that is currently available and being applied (i.e., an existing standard of care). When the standard care intervention and the therapy under study have comparable durations of treatment and client and therapist expectancies, the researcher can test the relative efficacy of the interventions. For example, in a recent RCT (Mufson et al., 2004), depressed adolescents were randomly assigned to interpersonal psychotherapy modified for depressed adolescents (IPT-A) or to "treatment-as-usual" in school-based mental health clinics. Adolescents treated with IPT-A compared to treatment-as-usual showed greater symptom reduction and improvement in overall functioning. Given the nature of their comparison group it can be inferred that the gains associated with IPT-A outperformed the existing standard of care for depressed adolescents in the community.

In standard treatment comparisons, it is important to ensure that both the standard (routine) treatment and the new treatment are implemented in a high-quality fashion (Kendall & Hollon, 1983). Using a standard treatment condition presents advantages over other conditions. Ethical concerns about no-treatment conditions are quelled, given that care is provided to all participants. Additionally, attrition is likely to be minimized and nonspecific factors are likely to be equated (Kazdin, 2003).

## Random Assignment

After comparison conditions have been selected, procedures for assigning participants to conditions must be chosen. *Random assignment* ensures that every participant has an equal chance of being assigned to the active treatment condition or the control condition(s). Random assignment of participants to the active therapy or control conditions and random assignment to study therapists are essential steps toward achieving initial comparability between conditions. However, note that random assignment does not guarantee comparability across treatment conditions—one resultant group may be different on key variables (e.g., age, wealth, impairment) simply due to chance. Appropriate statistical tests can be applied to examine the comparability of participants across treatment conditions.

Problems can arise when random assignment is not applied. Consider a situation in which participants do not have an equal chance of being assigned to the active and control condition. Suppose a researcher were to allow depressed participants to decide for themselves whether to participate in the active treatment or in a waitlist condition. If participants in the active treatment condition subsequently evidenced greater symptom reductions than waitlist participants, one would be unable to rule out the possibility that symptom differences could have resulted from pre-study differences between the participants (e.g., selection bias). Waitlist participants who elected to delay treatment may be individuals not ready to initiate work on their depression symptoms.

Random assignment does not absolutely assure comparability of conditions on all measures, but it does maximize the likelihood of comparability. An alternative procedure, randomized blocks assignment, or assignment by stratified blocks, involves matching prospective clients in subgroups that (a) contain clients that are highly comparable on key dimensions (e.g., initial severity) and (b) contain the same number of clients as the number of conditions. For example, if the study requires two conditions (a standard treatment and a new treatment), clients can be paired off so that each pair is highly comparable. The members in each pair are then randomly assigned to either condition, thus increasing the likelihood that each condition will contain relatively mirror-image participants while retaining the randomization factor. When feasible, randomized blocks assignment of clients to conditions can be a wise research strategy.

### Evaluating Response Across Time

To evaluate the effect of a treatment, it is essential to first evaluate the level of each client's functioning on the dependent variables before the intervention begins. Such pretreatment (or "baseline") assessments provide key data to inform whether clients are comparable at the beginning of treatment (i.e., between-groups comparisons), and whether clients' pretreatment levels of functioning differ significantly from functioning assessed at subsequent assessment points (i.e., within-groups comparisons).

Post-treatment assessments of clients are essential to examine the comparative efficacy of treatment versus control conditions. However, evidence of treatment efficacy immediately upon therapy completion may not be indicative of long-term success (maintenance). Treatment outcome may be appreciable at post-treatment but fail to exhibit maintenance of the effects at a follow-up assessment. It is highly recommended, and increasingly expected (Chambless & Hollon, 1998), that treatment outcome studies include a follow-up assessment. Follow-up assessments (e.g., 6 months, 1 year) are key to demonstrations of treatment efficacy and are a signpost of methodological rigor. For evidence of maintenance, the treatment must have produced results at the follow-up assessment that are comparable to those evident at post-treatment (i.e., improvements from pretreatment and an absence of detrimental change since post-treatment).

Follow-up evaluations can help to identify differential treatment effects. For example, the effects of two treatments may be comparable at the end of treatment, but one may be more effective in the prevention of relapse (see Greenhouse, Stangl, & Bromberg, 1989, for discussion of survival analysis). When two treatments are comparable at post-treatment, yet one has a higher relapse rate, the knowledge gained from the follow-up evaluation is a valuable rationale for selecting one treatment over another. For example, Brown and colleagues (1997) reported on a comparison of CBT and relaxation training as treatments for depression in alcoholism. Using the average (mean) days abstinent and drinks per day as dependent variables, measured at pretreatment and at 3 and 6 months post-treatment, the authors established that, although both treatments produced comparable initial gains, the cognitive-behavioral treatment was superior to relaxation training in maintaining gains.

Follow-up evaluations may also detect continued improvement—the benefits of some interventions may accumulate over time, and possibly expand to other domains of functioning. Researchers and policy-makers have become increasingly interested in expanding intervention research to consider potential indirect effects on the prevention of secondary problems. We followed-up individuals treated with a cognitive-behavioral treatment for childhood anxiety disorders roughly 7 years later (Kendall, Safford, Flannery-Schroeder & Webb, 2002). These data indicated that a meaningful percentage of treated participants had maintained improvements in anxiety and that positive responders, as compared with less-positive responders, had a reduced amount of substance-use involvement at long-term follow-up (see also Kendall & Kessler, 2002). It is important to note that gains identified at follow-up are best only attributed to the initial treatment after one determines that the participants did not seek or receive additional treatments during the follow-up interval.

As we learn more about the outcomes of treatment, we are intrigued by speculations about the process that takes place in achieving these outcomes. Some researchers are considering therapy process and outcome as intertwined and are assessing change during the course of treatment (i.e., intratreatment) as well as post-treatment and follow-up (e.g., Kazdin, Marciano, & Whitley, 2005; Kendall & Ollendick, 2004; Shirk, Gudmundsen, Kaplinski, & McMakin, 2008; Taft & Murphy, 2007). Repeated assessment of client symptoms and functional change suggests that the first several sessions of treatment constitute the period of most rapid positive change (Howard, Lueger, Maling, & Martiovich, 1993). However, change across several domains of functioning may be phasic and may require more extended treatment. Intratreatment assessments (see Lambert, Hansen, & Finch, 2001) not only permit a fine-grained mapping of the course of change in therapy, but also provide important clues (e.g., Jaycox, Foa, & Morral, 1998) to identify mediators (discussed later in this chapter) of positive or adverse outcomes.

### Multiple Treatment Comparisons

To determine comparative (or relative) efficacy and effectiveness of therapeutic interventions, researchers use between-groups designs with more than one active treatment condition. Between-groups designs are more direct comparisons of one treatment with one or more alternative treatments. Note that sample size considerations are influenced by whether the comparison is between a treatment and a control condition or one treatment versus

another known to be effective treatment (see Kazdin & Bass, 1989).

In multiple treatment comparisons, it is optimal when each client is randomly assigned to receive one and only one kind of therapy. The assignment of clients to conditions should result in the initial comparability of the clients receiving each intervention. As previously mentioned, a randomized block procedure, with participants blocked on an important variable (e.g., pretreatment severity), can be used. It is always wise to check the comparability of the clients in the different treatment conditions on other important variables (e.g., sociodemographic variables, prior therapy experience, treatment expectancies/preferences) before continuing with the evaluation of the intervention. If not all participants are available at the outset of treatment, such as when participants come from consecutive clinic admissions, then the comparability of conditions can be checked at several intervals as the therapy outcome study progresses toward completion.

Comparability across therapists administering the different treatments is essential. Therapists conducting each type of treatment should be comparable in (a) training, (b) professional and clinical experience, (c) expertise in the intervention, (d) allegiance with the treatment, and (e) expectation that the intervention will be effective. One method to control for therapist effects has each therapist conduct each type of intervention with at least one client per intervention. Another viable option is *stratified blocking*, which assures that each intervention is conducted by several comparable therapists. The first method has random assignment of therapists, but is preferred only when therapists are equally expert and positively disposed toward each intervention. For example, it would probably not be a valid test to ask a group of psychodynamic therapists to conduct both a CBT (in which their expertise is low) and a psychodynamic therapy (in which their expertise is high). As is often the case, it is wise to gather data on therapist variables (e.g., expertise, allegiance) and examine their relationships to outcomes.

Comparing alternative treatments requires that the intervention procedures across treatments be equated for salient variables such as (a) duration; (b) length, intensity, and frequency of contacts with clients; (c) credibility of the treatment rationale; (d) setting in which treatment is to be provided; and (e) degree of involvement of persons significant to the client. In some cases, these factors may be the basis for two alternative therapies (e.g., conjoint vs. individual marital therapy; or child- vs. family-based treatment). In such cases, the variable is the experimental contrast rather than a matter for control.

What is the best method of measuring change when two alternative treatments are being compared? Clearly, measures should not be differentially sensitive to one or the other treatment. The measures should (a) cover the range of functioning that is a target for change, (b) tap the costs and possible negative side effects, and (c) be unbiased with respect to the alternate interventions. Comparisons of therapies may be misleading if the assessments are not equally sensitive to the types of changes that are most likely caused by each type of intervention.

When comparing alternative treatments, the "expected efficacy" of each therapy based on prior studies requires consideration. Consider, for example, that two treatments are compared and that therapy A is found to be superior to therapy B. The question can then arise, was therapy A superior, or did therapy B fail to be efficacious in this instance? It would be desirable in demonstrating the efficacy of therapy A if the results due to therapy B reflected the level of efficacy typically found in earlier demonstrations of therapy B's efficacy. Interpretations of the results of comparative studies are dependent on the level of efficacy of each therapy in relation to its expected (or standard) efficacy. Effect sizes are useful in making these comparisons and in reaching sound conclusions.

Although the issues discussed apply, comparisons of psychological and psychopharmacological treatments (e.g., Dobson et al., 2008; Marcus et al., 2007; MTA Cooperative Group, 1999; Pediatric OCD Treatment Study Team, 2004; Walkup et al, 2008) present special issues. For example, how and when should placebo medications be used in comparison to or with psychological therapy? How should expectancy effects be addressed? How should differential attrition be handled? How is it best to handle intrinsic differences in professional contact across psychological and pharmacologic interventions? Follow-ups become especially important after the active treatments are discontinued. The question is especially pertinent given that psychological treatment effects may persist after treatment, whereas the effects of medications may not persist when the medications are discontinued. (Readers interested in discussions of these issues are referred to Hollon, 1996; Hollon & DeRubeis, 1981; Jacobson & Hollon, 1996a, 1996b).

## Matters of Procedure

We now consider procedural matters related to (a) defining the independent variable (the use of manual-based treatments), (b) checking the integrity of the independent variable (treatment fidelity checks), (c) selecting a sample, and (d) considering the research setting and the transportability of treatment.

### Defining the Independent Variable: Manual-based Treatments

It is essential that a treatment be adequately described and detailed in order to replicate an evaluation of the treatment, or to be able to show and teach others how to conduct the treatment. Accordingly, there is the need for the use of treatment manuals. Treatment manuals enhance internal validity and treatment integrity, and afford comparison of treatments across contexts and formats, while reducing confounds (e.g., differences in the amount of contact, type and amount of training, time between sessions). Therapist manuals facilitate training and contribute meaningfully to replication (Dobson & Hamilton, 2002; Dobson & Shaw, 1988).

Not all agree on the merits of manuals. Debate has ensued regarding the use of manual-based treatments versus a more variable approach typically found in practice (see Addis, Cardemil, Duncan, & Miller, 2006; Addis & Krasnow, 2000; Westen, Novotny, & Thompson-Brenner, 2004). Some argue that manuals limit therapist creativity and place restrictions on the individualization that the therapists use (see also Waltz, Addis, Koerner, & Jacobson, 1993; Wilson, 1995). Some treatment manuals appear "cook-bookish," and some lack attention to the necessary clinical sensitivities needed for proper individualization and implementation, but our experience suggests that this is not the norm. An empirical evaluation from our laboratory found that the use of a manual-based treatment for child anxiety disorders (Kendall & Hedtke, 2006) did not restrict therapist flexibility (Kendall & Chu, 1999). Although it is not the goal of manual-based treatments to have practitioners perform treatment in a rigid manner, this misperception has influenced some practitioners' openness to the use of manual-based interventions (Addis & Krasnow, 2000).

The proper use of manual-based therapy requires interactive training, flexible application, and ongoing supervision (Kendall & Beidas, 2007). Professionals cannot become proficient in the administration of therapy simply by reading a manual. As Barlow (1989) noted, effective use of manual-based treatments must be preceded by adequate training.

Several contemporary treatment manuals allow the therapist to attend to each client's specific needs, concerns, and comorbid conditions without deviating from the treatment strategies detailed in the manual. The goal is to include provisions for standardized implementation of therapy while utilizing a personalized case formulation (Suveg, Comer, Furr, & Kendall, 2006). Importantly, using manual-based treatments does not eliminate the potential for differential therapist effects. Within the context of manual-based treatments, researchers are examining therapist variables (e.g., warmth, therapeutic relationship-building behaviors) that might be related to treatment outcome (Creed & Kendall, 2005; Karver et al., 2008; Shirk et al., 2008).

### Checking the Integrity of the Independent Variable: Treatment Fidelity Checks

Quality experimental research includes checking the manipulated variable. In therapy outcome evaluations, the manipulated variable is typically treatment or a characteristic of treatment. By design, all clients are not treated the same. However, just because the study has been so designed does not guarantee that the independent variable (treatment) has been implemented as intended. In the course of a study—whether due to therapist variables, incomplete manual specification, poor therapist training, insufficient therapist monitoring, client demand characteristics, or simply error variance—the treatment that was assigned may not in fact be the treatment that was provided (see also Perepletchikova & Kazdin, 2005).

To help ensure that the treatments are indeed implemented as intended, it is wise to require that a treatment plan be followed, that therapists are trained carefully, and that sufficient supervision is available throughout. The researcher should conduct an independent check on the manipulation. For example, therapy sessions are audio- or videotaped, so that an independent rater can listen to/watch the tapes and conduct a manipulation check. Quantifiable judgments regarding key characteristics of the treatment provide the necessary check that the described treatment was indeed provided. Digital videotapes and audiotapes are inexpensive, can be used for subsequent training, and can be analyzed to answer other research questions. Tape recordings of the therapy sessions evaluated by outcome studies not only provide a check on the treatment within each separate study but also allow

for a check on the comparability of treatments provided across studies. That is, the therapy provided as CBT in one clinician's study could be checked to determine its comparability to other clinician-researchers' CBT.

Procedures from a recently completed clinical trial from our research program comparing two active treatment conditions for child anxiety disorders against an active attention control condition (Kendall et al., 2008) can illustrate integrity checks. First, we developed a checklist of the content/ strategies called for in each session by the respective manuals. A panel of expert clinicians serve as independent raters who used the checklists to rate randomly selected videotape segments from 20% of randomly selected cases. The panel of raters was trained on nonstudy cases until they reached an inter-rater reliability of .85 (Cohen's κ). Once reliable, the panel used the checklists to indicate whether the appropriate content was covered for randomly selected segments that were representative of all sessions, conditions, and therapists. A ratio was computed for each coded session: the number of checklist items covered by the therapist relative to the total number of items that should have been included. Results indicated that across the conditions, 85%–92% of intended content was in fact covered.

It is critical to also evaluate the *quality* of the treatment provided. A therapist may strictly adhere to the manual and yet fail to administer the therapy in an otherwise competent manner, or he or she may competently administer therapy while significantly deviating from the manual. In both cases, the operational definition of the independent variable (i.e., the treatment manual) has been violated, treatment integrity impaired, and replication rendered impossible (Dobson & Shaw, 1988). When a treatment fails to demonstrate expected gains, one can examine the adequacy with which the treatment was implemented (see Hollon, Garber, & Shelton, 2005). It is also of interest to study potential variations in treatment outcome that may be associated with differences in the *quality* of the treatment provided (Garfield, 1998; Kendall & Hollon, 1983). Expert judges are needed to make determinations of differential quality prior to the examination of differential outcomes for high- versus low-quality therapy implementation (see Waltz et al., 1993).

### Sampling Issues

Choosing a sample to best represent the clinical population about which you are interested in making inferences requires consideration. Debate exists over the preferred samples for treatment outcome research. A *selected sample* refers to a sample of participants who may need service but who may otherwise only approximate clinically disordered individuals. Randomized controlled trials, by contrast, apply and evaluate treatments with actual clients who are seeking services. Consider a study investigating the effects of treatment X on depression. The researcher could use (a) a sample of clinically depressed clients diagnosed via structured interviews (*genuine clinical sample*), (b) a sample consisting of a group of adults who self-report dysphoric mood (an *analogue sample*), or (c) a sample of depressed persons after excluding cases with suicidal intent, economic stress, and family conflict (*highly select sample*). This last sample may meet diagnostic criteria for depression but are nevertheless highly selected.

The benefits of using analogue or select samples may include a greater ability to control various conditions and minimize threats to internal validity, and from a practical standpoint researchers may find it easier to recruit these samples over genuine clinical samples. On the other hand, select and analogue samples compromise external validity— these are not the same people seen in typical clinical practice. With respect to depression, for instance, many question whether depression in genuine clinical populations compares meaningfully to self-reported dysphoria in adults (e.g., Coyne, 1994; Krupnick, Shea, & Elkin, 1986; Tennen, Hall, & Affleck, 1995; see also Ruscio & Ruscio, 2002, 2008). Researchers consider how the study results will be interpreted and generalized when deciding whether to use clinical, analogue, or select samples.

Researchers consider *client diversity* when deciding which samples to study. Historically, research supporting the efficacy of psychological treatments was conducted with predominantly European American samples—although this is rapidly changing (see Huey & Polo, 2008). One can question the extent to which efficacy findings from European American samples can be generalized to ethnic minority samples (Bernal, Bonilla, & Bellido, 1995; Bernal & Scharron-Del-Rio, 2001; Hall, 2001; Sue, 1998). Investigations have also addressed the potential for bias in diagnoses and in the provision of mental health services to ethnic minority patients (e.g., Flaherty & Meaer, 1980; Homma-True, Green, Lopez, & Trimble, 1993; Lopez, 1989; Snowden, 2003).

A simple rule is that the research sample should reflect the population to which the results will be

generalized. To generalize to a minority/diverse population, one must study a minority/diverse sample. Any barriers to care must be reduced and outreach efforts employed to inform minorities of available services (see Sweeney, Robins, Ruberu, & Jones, 2005; Yeh, McCabe, Hough, Dupuis, & Hazen, 2003). Walders and Drotar (2000) provide guidelines for recruiting and working with ethnically diverse samples.

Once sample diversity is accomplished, statistical analyses can examine potential differential outcomes (see Arnold et al., 2003; Treadwell, Flannery-Schroeder, & Kendall, 1994). Grouping and analyzing research participants by ethnic status is one approach. However, this approach is simplistic because it fails to address variations in individual client's degree of ethnic identity. It is often the degree to which an individual identifies with an ethnocultural group or community, and not simply his or her ethnicity itself, that may potentially moderate treatment outcome.

### Setting

Research determines treatment efficacy, but it is not sufficient to demonstrate efficacy within a narrowly defined sample in a highly selective setting. The question of whether the treatment can be transported to other settings requires independent evaluation (Southam-Gerow, Ringeisen, & Sherrill, 2006). Treatment outcome studies conducted in some settings (settings in which clients may differ on important variables) may not generalize to other settings. Some have questioned whether the outcomes found at select research centers will transport to clinical practice settings. One should study, rather than assume, that a treatment found to be efficacious within a research clinical setting will be efficacious in a clinical service setting (see Hoagwood, 2002; Silverman, Kurtines, & Hoagwood, 2004; Southam-Gerow et al., 2006; Weisz, Donenberg, Han, & Weiss, 1995; Weisz, Weiss, & Donenberg, 1992).

Closing the gap between clinical research and practice requires transporting effective treatments (getting "what works" into practice) and identifying additional research into those factors (e.g., client, therapist, researcher, service delivery setting; see Kendall & Southam-Gerow, 1995; Silverman et al., 2004) that may be involved in successful transportation. Fishman (2000) suggested that an electronic journal of case studies be assembled so that patient, therapy, and environmental variables can be collected/compiled from within naturalistic therapy settings. Although the methodology has flaws (Stricker, 2000), information technology–based approaches may facilitate more seamless integration of research and practice and foster new waves of outcome research.

### Matters of Measurement
#### Assessing the Dependent Variable(s)

No single measure serves as the sole indicator of clients' treatment-related gains. Rather, a variety of methods, measures, data sources, and sampling domains (e.g., symptomatic distress, functional impairment, quality of life) are used to assess therapy outcomes. A contemporary and rigorous study of the effects of therapy may use assessments of client self-report; client test/task performance; therapist judgments and ratings; archival or documentary records (e.g., health-care visit and costs, work and school records); observations by trained, unbiased, blinded observers; rating by significant people in the client's life; and independent judgments by professionals. Outcomes have more compelling impact when seen by independent (blind) evaluators than when based solely on the therapist's opinion or the client's self-reports.

The *multi-informant strategy*, in which data on variables of interest are collected from multiple reporters (e.g., client, family members, peers) can be particularly important when assessing children and adolescents. Features of cognitive development may compromise youth self-reports, and children may offer what they believe to be the desired responses. Thus, in RCTs with youth, collecting additional data from key adults in children's lives who observe them across different contexts (e.g., parents, teachers) is valued. However, because emotions and mood are partially internal phenomena, some symptoms may be less known to parents and teachers, and some observable symptoms may occur in situations outside the home or school.

An inherent concern with multi-informant assessment is that discrepancies among informants are to be expected (Comer & Kendall, 2004; Edelbrock, Costello, Dulcan, Conover, & Kalas, 1986). Research indicates low to moderate concordance rates among informants in the assessment of children and adolescents (Achenbach, McConaughy, & Howell, 1987; De Los Reyes & Kazdin, 2005). For example, cross-informant agreement in the assessment of childhood mood/anxiety can be low (Comer & Kendall, 2004; Grills & Ollendick, 2003).

A *multimodal strategy* relies on multiple inquiries to evaluate an underlying construct of interest. For example, assessing family functioning may include

family members completing self-report forms on their perceptions of family relationships, as well as conducting structured behavioral observations of family members interacting (to later be coded by independent raters). Statistical packages can integrate data obtained from multimodal assessment strategies. The increasing availability of handheld communication devices and personal digital assistants allows researchers to incorporate experience sampling methodology (ESM), in which people report on their emotions and behavior in the actual situation (*in situ*). These ESM data provide naturalistic information on patterns in day-to-day functioning.

Treatment evaluations use multiple targets of assessment. For example, one can measure overall psychological adjustment, specific interpersonal skills, the presence of a diagnosis, self-report mood, cognitive functioning, life environment, vocational status, and the quality of interpersonal relationships. No one target captures all, and using multiple targets facilitates an examination of therapeutic changes when changes occur, and the absence of change when interventions are less beneficial.

Broadly speaking, evaluation of therapy-induced change can be appraised on two levels: the specifying level and the impact level (Kendall, Pellegrini, & Urbain, 1981). The *specifying level* refers to the exact skills, cognitive or emotional processes, or behaviors that have been modified during treatment (e.g., examining the number of positive spousal statements generated during a specific marital relationship task). In contrast, the *impact level* refers to the general level of functioning of the client (e.g., absence of a diagnosis, functional status of the client). A compelling demonstration of beneficial treatment would include change that occurs at both the level of specific discrete skills and behaviors, and the impact level of generalized functioning in which the client interacts differently within the larger environmental context.

Assessing *multiple domains* of functioning provides a comprehensive evaluation of treatment, but it is rarely the case that a treatment produces uniform effects across the domains assessed. Suppose treatment A, relative to a control condition, improves depressed clients' level of depression, but not their overall psychological well-being. In an RCT designed to evaluate improved level of depression and psychological well-being, should treatment A be deemed efficacious if only one of two measures found gains? De Los Reyes and Kazdin (2006) propose the Range of Possible Changes model, which calls for a multidimensional conceptualization of intervention change. In this spirit, we recommend that researchers conducting RCTs be explicit about the domains of functioning expected to change and the relative magnitude of such expected changes. We also caution consumers of the treatment outcome literature against simplistic dichotomous appraisals of treatments as efficacious or not.

## Matters of Data Analysis

Contrary to popular misguided perceptions, data do not "speak" for themselves. *Data analysis* is an active process in which we extract useful information from the data we have collected in ways that allow us to make statistical inferences about the larger population that a given sample was selected to represent. Although a comprehensive statistical discussion is beyond the present scope (the interested reader is referred to Jaccard & Guilamo-Ramos, 2002a, 2002b; Kraemer & Kupfer, 2006; Kraemer, Wilson, Fairburn, & Agras, 2002) in this section, we discuss four areas that merit consideration in the context of research methods in clinical psychology: (a) handling missing data and attrition, (b) assessing clinical significance (i.e., the persuasiveness of outcomes), (c) mechanisms of change (i.e., mediators and moderators), and (d) cumulative outcome analyses.

### *Handling Missing Data and Attrition*

Given the time-intensive and ongoing nature of RCTs, not all clients who are assigned to treatment actually complete their participation in the study. A loss of research participants (*attrition*) may occur just after randomization, prior to post-treatment evaluation, or during the follow-up interval. Increasingly, clinical scientists are analyzing attrition and its predictors and correlates to elucidate the nature of treatment dropout, understand treatment tolerability, and to enhance the sustainability mental health services in the community (Kendall & Sugarman, 1997; Reis & Brown, 2006; Vanable, Carey, Carey, & Maisto, 2002). However, from a research methods standpoint, attrition can be problematic for data analysis, such as when there are large numbers of noncompleters or when attrition varies across conditions (Leon et al., 2006; Molenberghs et al., 2004).

No matter how diligently researchers work to prevent attrition, data will likely be lost. Although attrition rates vary across studies, Mason (1999) estimated that most researchers can expect nearly 20% of their sample to withdraw or be removed from a study before it is completed. To address this

matter, researchers can conduct and report two sets of analyses: (a) analyses of outcomes for the treatment completers and (b) analyses of outcomes for all clients who were included at the time of randomization (i.e., the *intent-to-treat sample*). An analysis of completers involves the evaluation of only those who completed treatment and examines what the effects of treatment are when someone completes its full course. Treatment dropouts, treatment refusers, and clients who fail to adhere to treatment schedules would not be included in these outcome analyses. In such cases, reports of treatment outcome may be somewhat high because they represent the results for only those who adhered to and completed the treatment. Intent-to-treat analyses, a more conservative approach to addressing missing data, require the evaluation of outcomes for all participants involved at the point of randomization. Proponents of intent-to-treatment analyses will say, "once randomized, always analyzed."

When conducting intent-to-treat analyses, the method used to handle missing endpoint data requires consideration, because different methods can produce different outcomes. Delucchi and Bostrom (1999) summarized the effects of missing data on a range of statistical analyses. Researchers address missing endpoint data via one of several ways: (a) *last observation carried forward* (LOCF), (b) substituting pretreatment scores for post-treatment scores, (c) multiple imputation methods, and (d) mixed-effects models.

The following example illustrates these different methods. Suppose a researcher conducts a smoking cessation trial comparing a 12-week active treatment (treatment A) to a 12-week waitlist control condition, with mean number of daily cigarettes used over the course of the previous week as the dependent variable, and with four assessment points: pretreatment, week 4, week 8, and post-treatment. A LOCF analysis assumes that participants who attrit remain constant on the outcome variable from their last assessed point through the post-treatment evaluation. If a participant drops out at week 9, the data from the week 8 assessment would be substituted for their missing post-treatment assessment data. A LOCF approach can be problematic however, as the last data collected may not be representative of the dropout participant's ultimate progress or lack of progress at post-treatment, given that participants may change after dropping out of treatment (e.g., cigarette use may abruptly rise upon dropout, reversing initially assessed gains). The use of pretreatment data as post-treatment data (a conservative and not

recommended method) simply inserts pretreatment scores for cases of attrition as post-treatment scores, assuming that participants who attrit make no change from their initial baseline state.

Critics of the LOCF and the pretreatment data substitution methods argue that these crude methods introduce systematic bias and fail to take into account the uncertainty of post-treatment functioning (see Leon et al., 2006). Increasingly, journals are calling for missing data imputation methods to be grounded in statistical theory and to incorporate the uncertainty regarding the true value of the missing data. *Multiple imputation methods* impute a range of values for the missing data (incorporating the uncertainty of the true values of missing data), generating a number of nonidentical datasets (typically five is considered sufficient; Little & Rubin, 2002). After the researcher conducts analyses on the nonidentical datasets, the results are pooled and the resulting variability addresses the uncertainty of the true value of the missing data. Moreover, *mixed-effects modeling,* which relies on linear and/or logistic regression to address missing data in the context of random (e.g., participant) and fixed effects (e.g., treatment, age, sex) (see Hedeker & Gibbons, 1994, 1997; Laird & Ware, 1982), can be used (see Neuner et al., 2008 for an example). Mixed-effects modeling may be particularly useful in addressing missing data if numerous assessments are collected throughout a treatment trial (e.g., weekly symptom ratings).

Given a lack of consensus regarding the most appropriate way to address missing data in RCTs, we encourage researchers—if it is possible for noncompleting participants to be contacted and evaluated at the time when the treatment protocol would have ended—to contact and reassess participants. This method controls for the passage of time, because both dropouts and treatment completers are evaluated over time periods of the same duration. If this method is used, however, it is important to determine whether dropouts sought and/or received alternative treatments in the interim.

## Clinical Significance: Assessing the Persuasiveness of Outcomes

The data produced by research projects designed to evaluate the efficacy of therapy are submitted to statistical tests of significance. The mean scores for participants in each condition are compared, the within-group and between-group variability is considered, and the analysis produces a numerical figure, which is then checked against critical values. An outcome achieves *statistical* significance if the

magnitude of the mean difference is beyond what could have resulted by chance alone (typically defined by convention as $p < .05$). Statistical analyses and statistical significance are essential for therapy evaluation because they inform us that the degree of change was likely not due to chance. However, statistical tests alone do not provide evidence of *clinical significance*.

Sole reliance on statistical significance can lead to perceiving differences (i.e., treatment gains) as potent when in fact they may not be clinically significant. For example, imagine that the results of a treatment outcome study demonstrate that mean Beck Depression Inventory (BDI) scores are significantly lower at post-treatment than pretreatment. An examination of the means, however, reveals only a small but reliable shift from a mean of 29 to a mean of 24. Given large sample sizes, this difference may well achieve statistical significance at the $p < .05$ level (i.e., over 95% chance that the finding is not due to chance alone), yet perhaps be of limited practical significance. At both pre- and post-treatment, the scores are within the range considered indicative of clinical levels of depressive distress (Kendall, Hollon, Beck, Hammen, & Ingram, 1987), and such a magnitude of change may have little effect on a person's perceived quality of life (Gladis, Gosch, Dishuk, & Crits-Christoph, 1990). Moreover, statistically meager results may disguise meaningful changes in client functioning. As Kazdin (1999) put it, sometimes a little can mean a lot, and vice versa.

*Clinical significance* refers to the meaningfulness or persuasiveness of the magnitude of change (Kendall, 1999). Whereas tests of statistical significance address the question "Were there treatment-related changes?" tests of clinical significance address the question "Were the treatment-related changes convincing and meaningful?" In the treatment of a depressive disorder, for example, clinically significant changes would have to be of the magnitude that, after therapy, the person no longer suffered from debilitating depression. Specifically, this can be made operational as changes on a measure of the presenting problem (e.g., depressive symptoms) that result in the client's being returned to within normal limits on that same measure. Several approaches for measuring clinically significant change have been developed, two of which are *normative sample comparison* and *reliable change index*.

## NORMATIVE COMPARISONS

Clinically significant improvement can be identified using normative comparisons (Kendall & Grove, 1988), a method for operationalizing clinical significance testing. Normative comparisons (Kendall & Grove, 1988; Kendall, Marrs-Garcia, Nath, & Sheldrick, 1999) can be conducted in several steps. First, the researcher selects a normative group for post-treatment comparison. Given that several well-established measures provide normative data (e.g., the Beck Depression Inventory, the Child Behavior Checklist), investigators may choose to rely on these preexisting normative samples. However, when normative data do not exist, or when the treatment sample is qualitatively different on key factors (e.g., age, socioeconomic status), it may be necessary to collect one's own normative data.

In typical research, when using statistical tests to compare groups, the investigator assumes that the groups are equivalent (null hypothesis) and wishes to find that they are not (alternate hypothesis). However, when the goal is to show that treated individuals are equivalent to "normal" individuals on some factor (i.e., are indistinguishable from normative comparisons), traditional hypothesis-testing methods are inadequate. To circumvent this problem, one uses an equivalency testing method (Kendall, Marrs-Garcia, et al., 1999) that examines whether the difference between the treatment and normative groups is within some predetermined range. Used in conjunction with traditional hypothesis testing, this approach allows for conclusions about the equivalency of groups (see e.g., Jarrett, Vittengl, Doyle, & Clark, 2007; Kendall et al., 2008; Pelham et al., 2000; Westbrook & Kirk, 2007; for examples of normative comparisons), thus testing that post-treatment case are within a normative range on the measure of interest.

## THE RELIABLE CHANGE INDEX

Another method to the examining clinically significant change is the Reliable Change Index (RCI; Jacobson, Follette, & Revenstorf, 1984; Jacobson & Traux, 1991). The RCI involves calculating the number of clients moving from a dysfunctional to a normative range. The RCI is a calculation of a difference score (post- minus pre-treatment) divided by the standard error of measurement (calculated based on the reliability of the measure). The RCI is influenced by the magnitude of change and the reliability of the measure (for a reconsideration of the interpretation of RCI, see Hsu, 1996). The RCI has been used in clinical psychological research, although its originators point out that it has at times been misapplied (Jacobson, Roberts, Berns, & McGlinchey, 1999). When used in conjunction

with reliable measures and appropriate cutoff scores, it can be a valuable tool for assessing clinical significance.

## CONCLUDING COMMENTS ON CLINICAL SIGNIFICANCE

Although progress has been made regarding the operationalization of clinical significance, some debate exists over how to improve its measurement (see Beutler & Moleiro, 2001; Blanton & Jaccard, 2006; Jensen, 2001). Whereas some researchers propose more advanced methods of normative comparison and analysis (e.g., using multiple normative samples), others suggest that clinical significance remain as a simple, client-focused, and practical adjunct to statistical significance results (Follette & Callaghan, 1996; Martinovich, Saunders, & Howard, 1996; Tingey, Lambert, Burlingame & Hansen, 1996).

Evaluations of statistical and clinical significance are most informative when used in conjunction with one another, and it is becoming more common for reports of RCTs to include evaluations of both. Statistically significant improvements are not equivalent to "cures," and clinical significance is a complementary, not a substitute, evaluative strategy. Statistical significance is required to document that changes were beyond those that could be expected due to chance alone—yet, it is also useful to consider if the changes returned dysfunctional clients to within normative limits on the measures of interest.

## Evaluating Mechanisms of Change: Mediators and Moderators of Treatment Response

When evaluating treatment efficacy, it is of interest to identify (a) the conditions that dictate when a treatment is more or less effective, and (b) the processes through which a treatment produces change. Addressing such issues necessitates the specification of *moderator* and *mediator* variables (Baron & Kenny, 1986; Holmbeck, 1997; Kraemer et al., 2002; Shadish & Sweeney, 1991). A moderator is a variable that delineates the conditions under which a given treatment is related to an outcome. Conceptually, moderators identify *on whom* and *under what circumstances* treatments have different effects (Kraemer et al., 2002). Functionally, a moderator is a variable that influences either the direction or the strength of a relationship between an independent variable (treatment) and a dependent variable (outcome). For example, if a given treatment were found to be more effective with women than with men, gender would be considered a moderator of the association between treatment and outcome. A mediator, on the other hand, is a variable that serves to explain the process by which a treatment impacts on an outcome. Conceptually, mediators identify *how* and *why* treatments have effects (Kraemer et al., 2002). If an effective treatment for child conduct problems was found to impact on the parenting behavior of mothers and fathers, which in turn were found to have a significant impact on child problem behavior, then parent behavior would be considered to mediate the treat-to-outcome relationship (provided certain statistical criteria were met; see Holmbeck, 1997). Let's take a closer look at each of these notions.

## MODERATORS

Treatment moderators help clarify for clinicians (and other consumers of the treatment outcome literature) which clients might be most responsive to a particular treatment (and for which clients alternative treatment might be sought). They have historically received more attention in the research literature than mediators of effectiveness. Moderator variables that have received the most attention include client age, client ethnicity, client gender, problem type, problem severity, therapist training, mode of delivery (e.g., individual, group, family), setting, and type and source of outcome measure (e.g., Dimidjian et al., 2006; Kolko, Brent, Baugher, Bridge, & Birmaher, 2000; McBride, Atkinson, Quilty, & Bagby, 2006; Owens et al., 2003; Shadish & Sweeney, 1991; Weisz, Weiss, Han, Granger, & Morton, 1995).

How does one test for the presence of a moderator effect? A moderator effect is an interaction effect (Holmbeck, 1997) and can be evaluated using multiple regression analyses or analyses of variance (ANOVA). When using multiple regression, the predictor (e.g., treatment vs. no treatment) and proposed moderator (e.g., age of client) are main effects and are entered into the regression equation first, followed by the interaction of the predictor and the moderator. Alternatively, if one is *only* interested in testing the significance of the interaction effect, all of these terms can be entered simultaneously (see Aiken & West, 1991). If one is using ANOVA, the significance of the interaction between two main effects is tested in an analogous manner: a moderator, like an interaction effect, documents that the effects of one variable (e.g., treatment) are different across different levels of another variable (i.e., the moderator).

The presence of a significant interaction tells us that there is significant moderation (i.e., that the association between the treatment variable and the outcome variable differs significantly across different levels of the moderator). Unfortunately, it tells us little about the specific conditions that dictate whether or not the treatment is significantly related to the outcome. For example, if a treatment-by-age interaction effect is significant in predicting treatment-related change, we know that the effect of the treatment for older clients differs from the effect of the treatment for younger clients, but we do not know whether the treatment effect is statistically significant for either age group. One would not yet know, based on the initial significant interaction effect, whether the relationship between treatment and outcome was significant for the older group, the younger group, or both groups.

Thus, when testing for moderation of treatment effects, statistically significant interactions must be further scrutinized. One such *post-hoc probing* approach is to plot and test the significance of simple slopes of regression lines for high and low values of the moderator variable (Aiken & West, 1991; Kraemer et al., 2002). Alternatively, one can test the significance of simple main effects via ANOVA procedures when the predictor (e.g., treatment vs. no treatment) and moderator (e.g., gender) are both categorical variables.

### MEDIATORS

A *mediator* is that variable that specifies the process through which a particular outcome is produced. The mediator effect elucidates the mechanism by which the independent variable (e.g., treatment) is related to outcome (e.g., treatment-related changes). Thus, mediational models are inherently causal models, and in the context of an experimental design (i.e., random assignment), significant mediational pathways are suggestive of causal relationships. As noted by Collins, Maccoby, Steinberg, Hetherington, and Bornstein (2000), studies of parenting interventions inform us not only about the effectiveness (or lack thereof) of such interventions, but also about causal relations between potential parenting mediators and child outcomes. For example, Forgatch and DeGarmo (1999) administered a parent training treatment to a sample of recently divorced mothers (as well as controls) and found that treatment was associated with positive (or less-negative) changes in parenting behavior—and that changes in parenting behavior were linked with

changes in child behavior. This work not only provides preliminary evidence for the utility of a particular treatment approach, but also demonstrates that a prospective (and perhaps causal) link exists in the direction of parenting impacting on child outcome.

When testing for meditational effects, the researcher is usually interested in whether a variable "mediates" the association between a treatment and an outcome, such that the mediator accounts for (i.e., attenuates) part or all of this association. To test for mediation, one examines whether the following are significant: (1) the association between the predictor (e.g., treatment) and the outcome, (2) the association between the predictor and the mediator, and (3) the association between the mediator and the outcome, after controlling for the effect of the predictor. If these three conditions are first met, one then examines (4) whether the predictor-to-outcome effect is less after controlling for the mediator. A corollary of the first condition is that there initially should be a significant relationship between the treatment and the outcome for a mediator to serve its mediating role. If the treatment and outcome are not significantly associated, there is no effect to mediate. Such a bivariate association between treatment and outcome is not required for moderated effects.

The three prerequisite conditions for testing mediational effects can be tested with three multiple regression analyses (Baron & Kenny, 1986). The significance of the treatment-to-outcome path (condition 1 above) is examined in the first regression. The significance of the treatment-to-mediator path (condition 2) is examined in the second regression. Finally, the treatment and mediator variable are simultaneously employed as predictors (via simultaneous entry) in the third equation, where the outcome is the dependent variable. Baron and Kenny (1986) recommend using simultaneous entry (rather than hierarchical entry) in this third equation, so that the effect of the mediator on the outcome is examined after controlling for the treatment and the effect of the treatment on the outcome is examined after controlling for the mediator (borrowing from path analytic methodology; Cohen & Cohen, 1983). The significance of the mediator-to-outcome path in this third equation is a test of condition 3. The relative effect of the treatment on the outcome in this equation (when the mediator is controlled) in comparison to the effect of the treatment on the outcome in the first equation (when the mediator is

not controlled) is the test of the fourth condition. Specifically, the treatment should be less associated with the outcome in the third equation than was the case in the first equation (i.e., the association between treatment and the dependent variable is attenuated in the presence of the proposed mediator variable).

Consider the following example: Within a cognitive-behavioral treatment for childhood anxiety disorders, what changes within the clients mediate the identified positive outcomes? To test for mediation, Kendall and Treadwell (2007) computed three regression equations for each dependent variable. In the first, it was established that treatment condition (CBT) predicted the dependent variable (e.g., change on an established anxiety measure). The second equation established that treatment condition predicted the proposed mediator (i.e., changes in children's self-statements during the trial). In the third equation, it was established that changes in children's self-statements (i.e., the proposed mediator) independently predicted the dependent variable. Finally, the meditational hypothesis was confirmed when the independent variable (treatment) no longer significantly predicted the dependent variable when change in self-statements was entered into the equation. This study (Kendall & Treadwell, 2007) provided support that change in children's self-talk mediates the effects of cognitive-behavior treatment for childhood anxiety.

How much reduction in the total effect is necessary to support the presence of mediation? Some researchers have reported whether the treatment-to-outcome effect drops from significance (e.g., $p < .05$) to nonsignificance (e.g., $p > .05$) after the mediator is introduced into the model. This strategy may be flawed, however, because a drop from significance to nonsignificance may occur, for example, when a regression coefficient drops from .28 to .27, but may not occur when it drops from .75 to .35. In other words, it is possible that significant mediation *has not* occurred when the test of the treatment-to-outcome effect drops from significance to nonsignificance after taking the mediator into account. On the other hand, it is also possible that significant mediation *has* occurred even when statistical test of the treatment-to-outcome effect continues to be significant after taking the mediator into account. Thus, it has been recommended when reporting mediational tests to also include a significance test that examines whether the drop in the treatment-to-outcome effect achieves statistical significance when accounting for the impact of the proposed

mediator (see MacKinnon & Dwyer, 1993; Sobel, 1988 for details).

### Cumulative Outcome Analyses: From Qualitative Reviews to Meta-Analytic Evaluations

The literature examining the outcomes of diverse therapies is vast, and there is a need to integrate that which we have learned in a systematic, coherent, and meaningful manner. Several major cumulative analyses have undertaken the challenging task of reviewing and reaching conclusions with regard to the effects of psychological therapy. Some of the reviews are strictly qualitative and are based on subjective conclusions, whereas others have used tabulations of the number of studies favoring one type of intervention versus that of competing interventions (e.g., Beutler, 1979; Luborsky, Singer, & Luborsky, 1975). This approach uses a "box score" summary of the findings, and reviewers would compare rates of treatment success to draw conclusions about outcomes. Still other reviewers have used multidimensional analyses of the impact of potential causal factors on therapy outcome: *meta-analysis* (Smith & Glass, 1977).

Meta-analytic procedures provide a quantitative, accepted, and respected approach to the synthesis of a body of empirical literature. Literature reviews are increasingly moving away from the qualitative summary of studies to the quantitative analysis of the reported findings of the studies (e.g., Cooper & Hedges, 1994; Cooper & Rosenthal, 1980; Durlak, 1999; Rosenthal, 1984). By summarizing the magnitude of overall relationships found across studies, determining factors associated with variations in the magnitude of such relationships, and establishing relationships by aggregate analysis, meta-analytic procedures provide more systematic, exhaustive, objective, and representative conclusions than do qualitative reviews (Rosenthal, 1984). To understand the effects of psychological treatments, as well as the factors associated with variations in these effects, meta-analysis is a preferred tool with which to inform funding decisions, service delivery, and public policy.

Meta-analytic techniques are highly informative because they synthesize findings across multiple studies by converting the results of each investigation into a common metric (e.g., the effect size). The outcomes of different types of treatments can then be compared with respect to the aggregate magnitude of change reflected in such statistics across studies. The effect size is typically derived by

computing the difference between the reported means of the treatment group and control group at post-treatment, then dividing this difference by the pooled standard deviation of the two groups (Durlak, 1995). The more rigorous scientific journals now require authors to include effect sizes in their reports.

Assuming that one has decided to conduct a meta-analytic review, what are the steps involved in conducting a meta-analysis? After determining that a particular research area has matured to the point at which a meta-analysis is possible and the results of such an analysis would be of interest to the field, one conducts a literature search. Multiple methods of searching are often used (e.g., computer database searches, reviews of reference sections from relevant article, sending a table of studies to be included to known experts in the area to review for potential missing citations). A word of advice to the meta-analyzer: Do not rely solely on computer searches, because they routinely omit several important studies.

A decision that often arises at this point is whether studies of varying quality should be included (Kendall, Flannery-Schroeder, & Ford, 1999; Kendall & Maruyama, 1985). On the one hand, one could argue that studies of poor quality should not be included in the review, since such studies would not ordinarily be used to draw conclusions about the effectiveness of a given psychological therapy. On the other hand, decisions concerning whether a study is of poor versus good quality are often not straightforward. A study may have certain exemplary features and other less desirable features. By including studies that vary in quality, one can examine whether certain "quality" variables (e.g., select vs. genuine clinical cases) are associated with differential outcomes. For example, in a recent meta-analysis (Furr, Comer, Edmunds, & Kendall, 2008), studies were rated in terms of their methodological rigor: one point for addressing missing data, one point for including appropriate comparison groups, one point for using psychometrically sound measures, etc. The research can then examine the extent to which methodological quality is related to results.

Coding the results of specific studies is an important part of a meta-analysis. Decisions need to be made regarding what types of variables will be coded and how inter-rater reliability among coders will be assessed. For example, in a study that examined the outcomes of a psychological therapy, one might code the nature of the intervention, whether the treatment was conducted in clinically representative conditions (Shadish, Matt, Navarro, & Phillips, 2000), the number of sessions, the types of participants, the diagnoses of the participants, the age range, the gender distribution, the therapy administration method (e.g., group vs. individual), the qualifications of the therapists, the various features of the research design, and types of outcomes. Once variables such as these have been coded, the effect sizes are then computed. The methods employed to compute effect sizes should be specified. Another consideration is whether effect sizes will be weighted (for example, based on the sample sizes of the studies reviewed, methodological rigor of studies, etc.). Using sample size to weight study findings has historically been employed in meta-analyses as a way to approximate the reliability of findings (i.e., larger samples would expectedly yield more reliable estimates than smaller samples). However, researchers are increasingly weighting studies by inverse variance weights (i.e., $1/(SE)^2$, where SE = standard error), rather than sample size, as this provides a more direct weighting of study findings by reliability. By weighting by inverse variance weights, the researcher is weighting by precision—the smaller the SE, the more precise the effect size, and consequently the greater you want to represent that effect size when aggregating it with other effect sizes.

After computing the effect sizes and inverse variance weights across studies, and then computing an overall *weighted mean effect size* (and confidence interval) based on the inverse variance weights associated with each effect size, the researcher evaluates the adequacy of the mean effect size in representing the entire distribution of effects via homogeneity testing (i.e., homogeneity statistic, Q). This consists of comparing the observed variability in the effect size values with the estimate of variance that is expected from subject-level sampling error alone (Lipsey & Wilson, 2000). A stem-and-leaf plot can also be useful in determining the distribution of effect sizes. Often a researcher will specifically hypothesize that effect sizes will be significantly heterogenous, given that multiple factors (e.g., sample characteristics, study methodology, etc.) can systematically exert influences on documented treatment effects. If the distribution is not found to be homogeneous, the studies likely estimate different population mean effect sizes, and alternative procedures are required that are beyond the scope of this chapter (see Lipsey & Wilson, 2000).

The merits of integration and summation of the results of related outcome studies are recognized,

yet some cautions must be exercised in any meta-analysis. As noted earlier, one must check on the quality of the studies, eliminating those that cannot contribute meaningful findings due to basic inadequacies (Kraemer, Gardner, Brooks, & Yesavage, 1998). Consider the following: Would you accept the recommendation that one treatment approach is superior to another if the recommendation was based on inadequate research? Probably not. If the research evidence is methodologically unsound, it is insufficient evidence for a recommendation; it remains inadequate as a basis for either supporting or refuting treatment recommendations, and therefore it should not be included in cumulative analyses. If a study is methodologically sound, then regardless of the outcome, it must be included.

Caution is paramount in meta-analyses in which various studies are said to provide evidence that treatment is superior to controls. The exact nature of the control condition in each specific study must be examined, especially in the case of attention-placebo control conditions. This caution arises from the indefinite definition of attention-placebo control conditions. As has been noted, one researcher's attention-placebo control condition may be serving as another researcher's therapy condition! Meta-analyzers cannot tabulate the number of studies in which treatment was found to be efficacious in relation to controls without examining the nature of the control condition.

Currently, major efforts are being made to identify and examine those psychological treatments that can be considered empirically supported. These efforts take a set of "criteria" that have been proposed as required for a treatment to be considered empirically supported and review the reported research literature in search of studies that can be used to meet the criteria. Such reviews (e.g., Baucom, Shoham, Mueser, Daiuto, & Stickle, 1998; Compas, Haaga, Keefe, Leitenberg, & Williams, 1998; DeRubeis & Crits-Christoph, 1998; Kazdin & Weisz, 1998; Weisz, Jensen-Doss, & Hawley, 2006; Weisz, McCarty, & Valeri, 2006) and reactions to the approach (e.g., Beutler, 1998; Borkovec & Castonguay, 1998; Garfield, 1998; Goldfried & Wolfe, 1998) document not only that this approach is being applied, but also that there are treatments that meet the criteria of having been supported by empirical research.

## Matters of Reporting

Communicating study findings to the scientific community is the final stage of conducting an evaluation of treatment. A well-constructed and quality report will discuss findings in the context of previous related work (e.g., discussing how the findings build on and support previous work; discussing the ways in which findings are discrepant from previous work and why this may be the case), as well as consider limitations and shortcomings that can direct future theory and empirical efforts in the area.

When preparing a quality report, the researcher provides all of the relative information for the reader to critically appraise, interpret, and/or replicate study findings. Historically, there have been some inadequacies in the reporting of RCTs (see Westen et al., 2004 for a critique of past practices). In fact, inadequacies in the reporting of RCTs can result in bias in estimating the effectiveness of interventions (Moher, Schulz, & Altman, 2001; Shulz, Chalmers, Hayes, & Altman, 1995). To maximize transparency in the reporting of RCTs, an international group of epidemiologists, statisticians, and journal editors developed a set of consolidated standards of reporting trials (i.e., CONSORT; see Begg et al., 1996), consisting of a 22-item checklist of study features that can bias estimates of treatment effects, or that are critical to judging the reliability or relevance of study findings, and consequently should be included in a comprehensive research report. A quality report will address each of these 22 items. For example, the title and abstract are to include how participants were allocated to interventions (e.g., randomly assigned), the methods must clearly detail eligibility criteria (i.e., inclusion/exclusion criteria) and how the sample size was determined, the procedures must indicate whether or not evaluators were blind to treatment assignment, and baseline demographic characteristics must be included for all participants. Importantly, participant flow must be characterized at each stage. The researcher reports the specific numbers of participants randomly assigned to each treatment condition, who received treatments as assigned, who participated in post-treatment evaluations, and who participated in follow-up evaluations (see Figure 4.1 for an example from Kendall et al., 2008). It has become standard practice for scientific journals to require a CONSORT flow diagram.

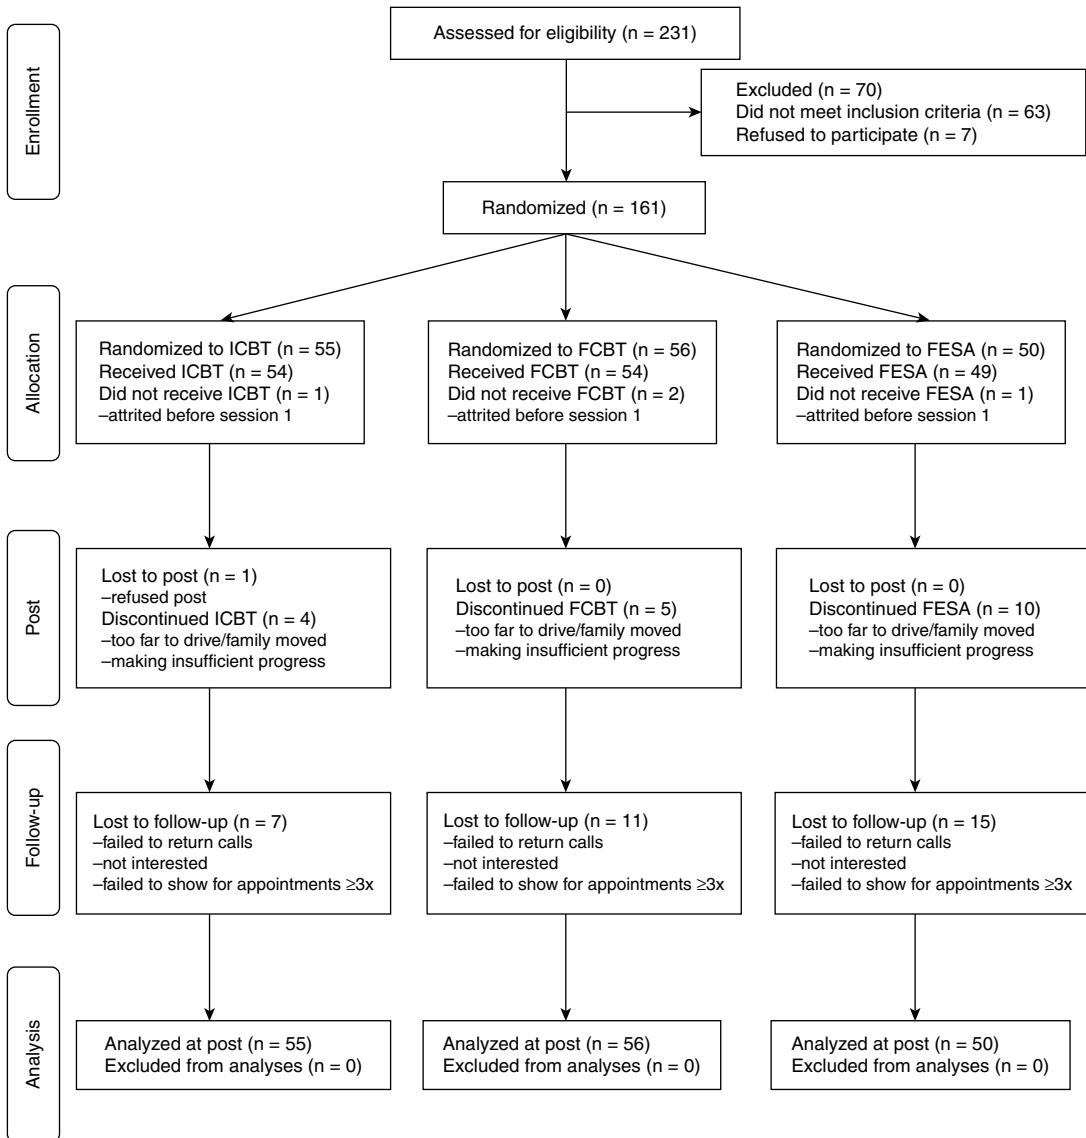
When the researcher has prepared a quality report that he or she deems is ready to be communicated to the academic community, the next decision is where to submit the report. When communicating the results of a clinical evaluation to the scientific community, the researcher should only consider submitting the report of their findings to a peer-reviewed journal.


**Figure 4.1** Example of flow diagram used in reporting to depict participant flow at each stage of a study. From Kendall, P. C., Hudson, J.L., Gosch, E., Flannery-Schroeder, E., & Suveg, C. (2008). Cognitive-behavioral therapy for anxiety disordered youth: A randomized clinical trial evaluating child and family modalities. *Journal of Consulting and Clinical Psychology, 76,* 282–297. Reprinted with permission of the publisher, the American Psychological Association (APA).

Publishing the outcomes of a study in a refereed journal (i.e., one that employs the peer-review process) signals that the work has been accepted and approved for publication by a panel of qualified and impartial reviewers (i.e., independent scientists knowledgeable in the area but not involved with the study). Consumers should be highly cautious of studies published in journals that do not place manuscript submissions through a rigorous peer-review process.

Although the peer-review process slows down the speed with which one is able to communicate study results (much to the chagrin of the excited researcher who just completed an investigation), it is nonetheless one of the indispensable safeguards that we have to ensure that our collective knowledge base is drawn from studies meeting acceptable standards. Typically, the review process is "blind," meaning that the authors of the article do not know the identities of the peer-reviewers who are considering

their manuscript. Many journals employ a double-blind peer-review process, in which the identities of study authors are also not known to the peer-reviewers.

## Conclusion

Having reviewed matters of design, procedure, measurement, data analysis, and reporting that are pertinent, one recognizes that no one single study, even with optimal design and procedures, can answer the relevant questions about the efficacy and effectiveness of therapy. Rather, a series and collection of studies, with varying approaches, is necessary. The criteria for determining empirically supported treatments have been proposed, and the quest for identification of such treatments continues. The goal is for the research to be rigorous, with the end goal being that the most promising procedures serve professional practice and those in need of services.

Therapy outcome research plays a vital role in facilitating a dialogue between scientist-practitioners and the public and private sector (e.g., Department of Health and Human Services, insurance payers, policy-makers). Outcome research is increasingly being examined by both managed care organizations and professional associations with the intent of formulating practice guidelines for cost-effective psychological care that provides maximal service to those in need. There is the risk that psychological science and practice will be co-opted and exploited in the service only of cost-containment and profitability: Therapy outcome research must retain scientific rigor while enhancing the ability of practitioners to deliver effective procedures to individuals in need.

# Evidence-based Assessment

John Hunsley *and* Eric J. Mash

**Abstract**

Evidence-based assessment relies on research and theory to inform the selection of constructs to be assessed for a specific assessment purpose, the methods and measures to be used in the assessment, and the manner in which the assessment process unfolds. An evidence-based approach to clinical assessment necessitates the recognition that, even when evidence-based instruments are used, the assessment process is a decision-making task in which hypotheses must be iteratively formulated and tested. In this chapter, we review (a) the progress that has been made in developing an evidence-based approach to clinical assessment in the past decade and (b) the many challenges that lie ahead if clinical assessment is to be truly evidence-based.

**Key Words:** Assessment, evidence-based assessment, evidence-based instruments, clinical decision-making

Assessment is ubiquitous in our society. At birth, babies are weighed, measured, and evaluated. In educational systems, students are assessed virtually every day from the time they begin school until they complete their education many years later. In the employment domain, people are repeatedly evaluated, either formally or informally, for myriad reasons, such as determining whether they should be offered a job, allowed to continue in the job, receive promotions, and receive salary increases. Every appointment with a health-care professional, including dentists, optometrists, and physicians, involves an evaluation of the patient's health, presenting complaints, and potential for rehabilitation, amelioration of symptoms, or cure. Assessment, in one form or another, is a central and inescapable aspect of our lives in the 21st century.

There can be no doubt about the critical role that assessment has in psychology. For many psychologists, core elements of the discipline include (a) our heritage of striving to accurately measure and evaluate a host of human phenomena and (b) our development of strategies, tools, and statistics to achieve these goals (Benjamin, 2005). Likewise, for many clinical psychologists, expertise in clinical assessment is seen as a unique and defining feature of the profession, one that sets us apart from other disciplines involved in providing health-care services (Krishnamurthy et al., 2004). Historically, assessment was an integral component in the development of the profession of clinical psychology, and it remains one that is clearly evident in the contemporary practice of clinical psychology. Indeed, it is hard to conceive of assessment *not* occurring in situations in which psychological services are provided, research is conducted, or psychological policy decisions are made.

The fact that something is ubiquitous and integral to some aspect of life does not mean that it is always valued as highly or examined as closely as it should be. As an example, we tend to take for granted having ready access to electricity to power our homes, offices, and numerous electronic devices. It may be only when storms disrupt the electrical transmission grid, or when blackouts occur for other reasons, that our

reliance on electricity to run our personal and professional lives comes into sharp focus. The very centrality of electrical power in our lives makes us rather complacent about its value and importance, and probably leads us to be rather unquestioning in our acceptance of our need for it. From our perspective, the very successful history of measurement, test development, and assessment within psychology, generally, and clinical psychology, specifically, has, likewise, left psychologists complacent about the nature and value of psychological assessment methods and processes. Because of the assumptions, at least among psychologists, that psychological assessment is important and that clinical psychologists are well-equipped to conduct assessments that inform psychological services, the usefulness of contemporary assessment instruments and practices has rarely been questioned. For example, there is little solid evidence to support the usefulness of assessment for improving treatment outcomes, and many commonly used assessment methods have limited or contradictory empirical support (e.g., Fletcher, Francis, Morris, & Lyon, 2005; Hunsley, Lee, Wood, & Taylor, in press; Norcross, Koocher, & Garofalo, 2006). As a result, at this point in time, any requests from program administrators, third-party payers, or clients to justify the professional time and costs associated with psychological assessment cannot be convincingly addressed with empirical data.

The neglect of such a basic question as the usefulness of current assessment practices in professional practice also reflects the influence of other factors, including (a) a belief in the intrinsic worth of many established and commonly used assessment methods (e.g., intelligence tests and projective personality tests) and (b) a lack of clarity regarding the kinds of evidence and criteria needed to evaluate the utility of assessment methods and processes. As a result, systematic evaluations of the way in which clinicians integrate and use assessment information in case formulation, treatment planning, or treatment monitoring activities are only infrequently conducted (Fernandez-Ballesteros et al., 2001). Thus, rather than having a cumulative scientific literature on psychological assessment, we currently have an impressive and extremely large body of research on assessment instruments and instrument subscales. However, research on psychological measures is not the same as research on the more complicated task of psychological assessment, a task that involves integrating test results (including data from self-report measures, behavioral observations, performance tasks, and biologically based indices), life history

information, and collateral data into a coherent description of the client being assessed. Research on psychological instruments is a necessary component of, but not a substitute for, research on psychological assessment (Hunsley, 2002; McGrath, 2001), a point we will return to later in the chapter.

Fortunately, a modest but noticeable shift has occurred in the assessment literature, one that involves scientifically and professionally informed critical appraisals of the way in which psychological assessment research is conducted and psychological assessments are used to guide practice. This shift is due to many factors, including concerns about accountability of psychological services (e.g., Wood et al., 2002), the need to base assessment practices more fully on scientific evidence (e.g., Hunsley & Mash, 2005), the need for assessment research that is directly relevant to the practice of assessment (e.g., McGrath, 2001), the need to more fully consider assessment issues in treatment research and treatment provision (e.g., Mash & Hunsley, 2005), and, more broadly, the move toward evidence-based health-care practices (e.g., Institute of Medicine, 2001). One of the main results of the confluence of these factors has been the development of evidence-based assessment (EBA).

As we have written elsewhere (Hunsley & Mash, 2007), EBA is an approach to clinical evaluation that uses research and theory to guide the selection of constructs to be assessed for a specific assessment purpose, the methods and measures to be used in the assessment, and the manner in which the assessment process unfolds. Evidence-based assessment involves the recognition by the psychologist that, even when data from psychometrically strong measures are available, the assessment process is inherently a decision-making task in which the psychologist must iteratively formulate and test hypotheses by integrating data that may be incomplete or inconsistent. As a result, a truly evidence-based approach to assessment involves an evaluation of the accuracy and usefulness of this complex decision-making task in light of potential errors and biases in data synthesis and interpretation, the costs associated with the assessment process and, ultimately, the impact the assessment had on clinical outcomes for the person(s) being assessed. Defined in this manner, EBA is part of the larger evidence-based practice (EBP) movement that stresses the use of an amalgamation of systematically collected data, clinical expertise, and patient preferences by decision makers (including, but not limited to, clinicians) when considering services options for individual patients

or subgroups of the population (e.g., American Psychological Association Presidential Task Force on Evidence-Based Practice, 2006; Sackett et al., 1996).

Building on our previous work (e.g., Hunsley & Mash, 2007, 2008b; Mash & Hunsley, 2005), in this chapter we present the current state of development of EBA. We begin by highlighting the reasons that EBA is needed in clinical psychology, including problems with commonly used instruments and the lack of data on clinical utility. We then review efforts to conceptualize EBA and recent attempts to operationalize criteria for EBA. This is followed by an examination of how differences in these criteria affect whether an instrument is classified as being evidence-based. Finally, we discuss some of the challenges the field must address in building a truly evidence-based approach to clinical assessment.

## Some Current Problems and Limitations in Clinical Assessment

As just discussed, it appears that the weight of scientific evidence is not being used to its fullest extent in a number of areas in the domain of psychological assessment. In the following sections, we present some examples of the problems that underscore the importance of promoting an evidence-based approach to clinical assessment. We hasten to add that these problems do not mean that clinical assessment, in general, is lacking in merit or without value in the provision of health-care services to those being assessed. Rather, by focusing on problems associated with some frequently used instruments and common assessment practices, our intention to is to demonstrate ways in which clinical psychologists can improve upon their efforts to deliver high-quality care to the patients they serve and to provide scientifically based education to the trainees they teach and supervise.

## Scientific Limitations of Some Commonly Used Clinical Instruments

Over the years, there have been numerous surveys of the instruments most commonly used by clinical psychologists and taught in graduate training programs and internships. Despite some rather important advances in measurement and test development having occurred, survey after survey has shown that few clinicians engage in assessment practices that are consistent with evidence-based guidelines (Jensen-Doss, 2011). Moreover, the general patterns of instrument usage and the relative rankings of specific instruments have changed very little over at least 30 years (Piotrowski, 1999). These surveys indicate that, among the most commonly used and taught instruments are a number of assessment tools that have either little or mixed research support. As we describe in the following paragraphs, although many of these scientifically questionable tests are projective instruments, there are also problems with other types of frequently used measures.

The Rorschach inkblot test has been the focus of a number of literature reviews (e.g., Hunsley & Bailey, 2001, Meyer & Archer, 2001; Mihura, Meyer, Dumitrascu, & Bombel, in press; Wood, Nezworski, Lilienfeld & Garb, 2003). The Comprehensive System (CS; Exner, 1993) is now considered by Rorschach proponents as the principal scoring system for the Rorschach. The Rorschach is a very complex measure to administer, score, and interpret, and the CS provides very clear directions on its administration and scoring. Unfortunately, research indicates that even if these directions are followed, relatively innocuous contextual factors in Rorschach administration, such as the layout of the testing room and the appearance of the assessor, influence the responses produced by examinees (Masling, 1992). Moreover, the CS system can be very difficult to follow correctly. Guarnaccia, Dill, Sabatino, and Southwick (2001) found that both graduate students and psychologists made numerous errors in scoring the Rorschach. In fact, these errors were so extensive that the overall mean accuracy in scoring the main aspects of the CS was only 65%.

A longstanding concern with the CS norms is that they tend to overpathologize normal individuals, something that has been found in both child and adult research samples (Wood, Nezworski, Garb, & Lilienfeld, 2001). The nature of the concern is best illustrated by Hamel, Shaffer, and Erdberg's (2000) study involving data from 100 children who were selected for the absence of psychopathology and behavior problems based on historical information and assessment of current functioning. When the Rorschach data from these children were scored and interpreted according to CS norms, many of them scored in the clinical range on Rorschach indices of psychopathology. As Hamel and colleagues wrote (p. 291): "(T)hese children may be described as grossly misperceiving and misinterpreting their surroundings and having unconventional ideation and significant cognitive impairment. Their distortion of reality and faulty reasoning approach psychosis. These children would also be described as having significant problems establishing and maintaining interpersonal relationships and coping within a social context." However, based on the extensive data used to select these children for the study, none

had had psychological problems in the past, none were currently experiencing psychological distress, and all were doing very well in school and in social activities.

Questions about the CS norms resulted in efforts to develop norms that meet the standards required of psychological tests. A series of norms, called the International Reference Samples, were published for the CS, based on data from over 5,800 people from 16 countries (Shaffer, Erdberg, & Meyer, 2007). Taken together, these norms are now recommended for scoring and interpreting adults' responses to the Rorschach (Meyer, Erdberg, & Shaffer, 2007). Although many of the problems with the previous adult norms are said to have been addressed with these new norms, major problems arose in trying to develop norms for youth. Substantial and erratic differences in CS scores occurred both within and across samples from the various countries. This resulted in the main researchers in the international norming effort recommending against using available norms for Rorschach responses from children and adolescents (Meyer et al., 2007). This means that, essentially, the Rorschach should not be used as a psychological test with youth. The scientifically appropriate position taken by these researchers stands in direct contrast with frequent claims that using the Rorschach with youth is consistent with ethical and professional standards for psychological test usage (Hughes, Gacono, & Owens, 2007). Because of these and other problems with the CS, a group of prominent Rorschach researchers have developed an alternative scoring system (http://www.r-pas.org). Only time (and research) will tell whether this scoring system will address the multitude of problems with the CS.

Another example of an instrument that is frequently used by clinical psychologists despite the lack of evidence for its reliability or validity is the Thematic Apperception Test (TAT; Murray, 1943). Although reliable and valid scoring systems for apperceptive tests are employed in research contexts (e.g., Spangler, 1992), they have not been adopted in clinical practice. Very little has changed over several decades of TAT research: There continues to be enormous variability in the manner in which the test is administered, scored, and interpreted, and there is no cumulative evidence that supports the test's reliability and validity (Rossini & Moretti, 1997). Most important, for a clinical instrument, there are repeated negative findings in the literature that many approaches to scoring the TAT are simply incapable of differentiating between research participants with mental disorders and those with no

mental disorders (Lilienfeld, Wood, & Garb, 2000). Despite its popularity with some psychologists, the TAT is clearly a psychological test that falls well short of professional standards for tests (cf. McGrath & Carroll, 2012).

A very similar set of problems, in terms of scoring systems and the lack of established reliability and validity, is encountered with the various types of projective drawing tests. In his review of the literature, Lally (2001) concluded that the most frequently used approaches to scoring projective drawings failed to meet legal standards for a scientifically valid technique. Commenting on the scoring systems for projective drawings developed within research contexts, he indicated that they fared somewhat better than other systems. Nevertheless, he summarized their scientific status in the following manner: "(a)lthough their validity is weak, their conclusions are limited in scope, and they appear to offer no additional information over other psychological tests, it can at least be argued that they cross the relatively low hurdle of admissibility (p. 146)." For clinicians looking to provide scientifically based assessments for their clients, this is certainly damning with faint praise. Based on research conducted since Lally's review, there is still little evidence supporting the value of projective drawing tests (McGrath & Carroll, 2012).

Thus far, we have focused on commonly used projective tests, but there are also problems, albeit less serious ones, evident in other types of psychological tests. For example, the Symptom Checklist 90-Revised (Derogatis, 1992) is frequently used in a range of clinical settings to assess patients' psychological problems and symptoms. It has nine subscales assessing primary symptom dimensions such as depression, phobic anxiety, psychoticism, and interpersonal sensitivity, along with three summary scores that assess overall symptom levels and distress. It has been known for well over two decades that the factor structure of the test is not consistent with the use and interpretation of the subscales (Cyr, McKenna-Foley, & Peacock, 1985), and more recent studies continue to indicate that there is a single underlying general factor evident in the test (e.g., Holi, Sammallahti, & Aalberg, 1998; Olsen, Mortensen, & Bech, 2004). The repeated finding of this single factor, best conceptualized as a broad dimension of distress, strongly indicates that interpreting the subscales in a substantive manner (i.e., as indicating the presence of elevated symptoms of depression, phobic anxiety) is unlikely to be appropriate. Without a clear sense of how best to inter-

pret the validity of the scales of this self-report measure, there may be considerable problems with the construct validity of the various short-form versions of this test—a concern that is not unique among the plethora of short forms developed for psychological measures (Smith, 2000).

## Problems with Instrument Selection and Interpretation

Even if clinical psychologists refrain from using instruments that have limited scientific support, they must still ensure that the instruments they choose to use are appropriate for the assessment task and are interpreted in accordance with the scientific evidence. Although these would seem to be rather self-evident requirements, there are numerous examples in the professional literature in which these requirements are not met or are simply ignored. As assessments conducted by clinical psychologists often have substantial impact on the people who are assessed (e.g., psychoeducational assessments that will largely determine access to additional educational supports and resources and disability assessments that will affect the possible awarding of disability pensions), it is critical that instruments are selected and used in a professionally responsible manner.

Many clinical psychologists conduct evaluations that are used to inform the courts in determining child custody decisions. These evaluations are expected to provide fair and balanced information about all parties relevant to child custody decisions, and guidelines for conducting these assessments have been available to psychologists and other health professionals for many years (e.g., American Academy of Child and Adolescent Psychiatry, 1997; American Psychological Association, 1994). However, there continue to be many problems with the way in which some clinical psychologists undertake these assessments. One survey of psychologists who frequently conducted child custody evaluations found that projective tests were often used to assess child adjustment (Ackerman & Ackerman, 1997). As described in the previous section, these types of tests rarely have appropriate levels of reliability and validity, and are unlikely to have valid norms. Without evidence of strong psychometric properties, it is all but impossible to make accurate determinations about the psychological adjustment of those tested. For reasons such as these, the recent guidelines of the Association of Family and Conciliation Courts (AFCC, 2006) stressed the need for assessors to use assessment methods that are empirically based and warn against using instruments with questionable reliability or validity. As valuable as such guidelines may be, there is compelling evidence that professional guidelines are not always closely followed. Horvath, Logan, and Walker (2002) examined child custody evaluation reports included in court records and conducted content analyses to determine the extent to which key aspects of these guidelines were met in the evaluations. They found evidence of many gaps in the reports as, for example, evaluators often failed to assess general parenting abilities and the ability of each parent to meet his or her child's needs—key elements of any assessment intended to provide guidance on the issue of child custody.

Fortunately, in some assessment areas there is clear evidence that practices are being influenced by research findings. Lally (2003) surveyed experts in forensic assessment to derive recommendations for which psychological tests should be used for assessment tasks such as malingering, mental state at the time of the criminal offence, risk for future violence or sexual violence, competency to stand trial, and competency to waive rights regarding self-incrimination. For most of these assessment tasks, among the instruments that were recommended or deemed acceptable were recently developed tests designed to specifically address the assessment question and repeatedly validated for that purpose (such as the Violence Risk Appraisal Guide [Rice & Harris, 1995] for the prediction of future violence and the Test of Memory Malingering [Rees, Tombaugh, Gansler, & Moczynski, 1998] for the assessment of malingering). On the other hand, consistent with the scientific evidence in this area, projective tests were routinely described as unacceptable for these forensic assessment tasks.

Even when a psychometrically robust measure is used, challenges can still arise in accurately interpreting the test data. This fact is abundantly evident in the literature on the Wechsler intelligence scales, tests that are among the psychometrically strongest psychological instruments available. A wealth of information exists on the importance of using country-specific norms for the interpretation of the Wechsler intelligence scales. For example, Kamieniecki and Lynd-Stevenson (2002) found that Australian children obtained slightly higher IQ scores than did American children of a similar age. This means that, as was typically done in the past, using American norms in the assessment of intellectual giftedness or disability among Australian children would result in some classification errors. Similarly, the use of American norms, rather than the Canadian norms, for the adult intelligence scale leads to a significant underestimation of the extent of cognitive impairment experi-

enced by Canadian patients with substantial neuropsychological problems (Iverson, Lange, & Viljoen, 2006). Findings such as these underscore the importance of recent efforts to develop country-specific norms for the Wechsler scales in English-speaking countries outside of the United States.

Beyond the use of appropriate norms, there is another problem with the interpretation of the Wechsler intelligence scales that is likely quite widespread. Many of the professional books used by clinical psychologists as an aid to the interpretation of the scales recommend that, following a consideration of the full scale IQ score, the verbal and performance IQ scores, and the factor scores, the next interpretive step should be to examine the variability between and within subtests (e.g., Flanagan & Kaufman, 2004; Kaufman & Lichtenberger, 1999). There are at least two problems with such a recommendation. First, as the internal consistency of each subtest is lower than that associated with the IQ and factor scores, the ability assessed by each subtest is measured less precisely, which means that there will be an increased likelihood of false positive and false negative conclusions drawn about the ability measured by the subtest. Second, beyond the issue of measurement and decision-making errors, there is substantial evidence over several decades that the information contained in subtest profiles adds little to the prediction of either learning behaviors or academic achievement once IQ scores and factor scores have been taken into account (Watkins, 2003).

## Limited Evidence for Clinical Utility of Commonly Used Instruments

The concept of clinical utility is being used increasingly in evaluations of the value of both diagnostic systems (e.g., First et al., 2004; Kendell & Jablensky, 2003; Uher & Rutter, 2012) and psychological assessment instruments (e.g., Hunsley & Bailey, 1999; McFall, 2005; Yates & Taub, 2003). In the context of diagnostic systems, utility refers to the extent to which a classification system provides nontrivial information about prognosis or treatment outcome and/or provides testable propositions about variables associated with a patient's diagnosis (Kendell & Jablensky, 2003). With respect to psychological instruments, clinical utility refers to whether the use of test data improve upon typical clinical decision-making and treatment outcome or, in other ways, make a difference in terms of the client's functioning as a result of clinical services informed by the test data (Hunsley & Bailey, 1999). Although the definitions vary, a common emphasis is placed on garnering evidence regarding actual improvements in both decisions made by clinicians and service outcomes experienced by patients. To date, despite thousands of studies on the psychometric properties of psychological instruments, only scant attention is paid to matters of utility in the assessment research literature (McGrath, 2001). In other words, we have very little evidence that psychological assessment data have a direct impact on the improved provision and outcome of clinical services.

In the past two decades, many authors have commented on the limited attention paid to the utility of widely used assessment instruments and methods with respect to treatment process and outcome (e.g., Hayes, Nelson & Jarrett, 1987). Diagnosis has some utility in determining the best treatment options for clients (i.e., by guiding clinicians to the evidence base on what treatments are most efficacious and effective for patients with the diagnosis or diagnoses in question). However, most psychologists consider diagnostic information as providing only one aspect of what is necessary in assessing clients seeking treatment. At this point, there is extremely little replicated evidence regarding the extent to which other data gathered in a clinical assessment contributes to beneficial treatment outcomes (Nelson-Gray, 2003). A study by Lima et al. (2005) illustrates the way in which research can begin to address the important set of questions inherent in the concept of clinical utility. In this study, clients completed the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) prior to commencing treatment; half the treating clinicians then received feedback on their client's MMPI-2 data, and half did not. The clients involved in the study presented with a range of diagnoses, including anxiety disorders, mood disorders, substance-related disorders, adjustment disorders, eating disorders, and personality disorders. To address questions of utility, the researchers conducted between-group comparisons on variables related to treatment outcome. They found that providing clinicians with the MMPI-2 results as a potential aid in treatment planning had no discernible impact on variables such as client improvement ratings or premature termination rates. These results illustrate that, even for instruments that have been extensively researched, such as the MMPI-2, an instrument should not automatically be assumed to possess utility for all the tasks for which it is commonly used.

## Conceptualizing and Evaluating Evidence-based Assessment

The current era of evidence-based health-care practices both requires and depends upon the use of

scientifically sound assessment methods, instruments, and strategies (Barlow, 2005). Without accurate assessment data, it is impossible to determine the psychosocial functioning of patients, monitor the treatments they are provided, evaluate the impact of these services at completion, evaluate the broader program in which the treatments are provided, or conduct ongoing quality assurance in order to enhance the functioning of the clinicians working in the program.

Considerable attention has been focused in the professional literature on the development, dissemination, and use of evidence-based treatments (EBTs) (Nathan & Gorman, 2007; Silverman & Hinshaw, 2008). Although EBTs have been hailed by many psychologists as the best option for providing optimal treatments to patients, a number of concerns about their general applicability and relevance remain. Kazdin (2008) summarized several fundamental issues that must be confronted in using EBTs in light of the nature of clinical practice. These included, for EBTs, variability in classification criteria used to designate a treatment as evidence-based or empirically supported, the real-world meaning of scores on psychological measures and the extent of changes on these measures necessary to indicate a clinically relevant change in functioning, and variability in the extent of treatment-related change observed in the multiple outcome measures used in any given treatment study. With respect to routine clinical practice, Kazdin noted that considerable progress needs to be made on the use of clinical expertise and decision-making to guide treatment formulation and provision, the manner in which clinical experience can be meaningfully and systematically used to inform service provision, and the use of systematic measurement to evaluate the impact of psychological services. Even a cursory review of these issues indicates that most, if not all, are essentially issues of measurement and the application of assessment data to inform clinical practice.

Yet, relative to the attention devoted to EBTs, matters pertinent to EBA have received scant attention (cf. Jensen-Doss, 2011). As Achenbach (2005) emphasized, the failure to draw upon the scientific literature on psychological assessment in developing and promoting EBTs is like constructing a magnificent house without bothering to build a solid foundation. Indeed, as the evaluation of, and, ultimately, the identification of EBTs rests entirely on the assessment data, ignoring the quality of psychological assessment instruments and the manner in which they are used places the promotion of evidence-based psychological practice in jeopardy. As an example, for a number

of psychological disorders, research-derived treatment benchmarks can now provide clinicians with meaningful and attainable targets for their intervention services (Hunsley & Lee, 2007; Lee, Horvath, & Hunsley, in press; Minami et al., 2008; Weersing, 2005). But, to be meaningful, these benchmarks must be based on reliable and valid measures, and to employ these benchmarks in routine practice, clinical psychologists must use assessment tools that have strong scientific support and are appropriate for the task at hand. Moreover, the decision-making processes surrounding how to determine relevant and appropriate benchmarks, obtain client data, and compare these data to the benchmarks must, themselves, be reliable and valid.

Across mental health professions, clinicians are seeking assessment tools they can use to determine a client's level of pretreatment functioning and to develop, monitor, and evaluate the services received by the client (Barkham et al., 2001; Bickman et al., 2000; Overington & Ionita, 2012). In their continuing efforts to improve the quality of mental health assessments, the American Psychiatric Association published the second edition of its *Practice Guideline for the Psychiatric Evaluation of Adults* (2006). Drawing from both current scientific knowledge and the realities of clinical practice, this guideline addressed both the content and process of psychiatric evaluations. It also built upon the *Handbook of Psychiatric Measures* (American Psychiatric Association, 2000), a publication that offers information to mental health professionals on the availability of self-report measures, clinician checklists, and structured interviews relevant to the provision of clinical services. For each measure reviewed, there is a brief summary of its intended purpose, psychometric properties, likely clinical utility, and the practical issues likely to be encountered in its use.

With respect to children and adolescents, the American Academy of Child and Adolescent Psychiatry and American Academy of Pediatrics have been active in developing practice guidelines for assessment instruments (e.g., self-report instruments) and contexts (e.g., family assessment), as well as for the assessment of specific childhood disorders (e.g., autistic spectrum disorders). These guidelines are based on the scientific literature and clinical consensus, and describe generally accepted approaches to assess specific disorders (e.g., Johnson, Myers, & the Council on Children with Disabilities, 2007). Thus, the need for developing EBA practices is apparent not only in clinical psychology but across a variety of health disciplines that, in some areas,

may be further along in this enterprise than professional psychology.

Psychology has a long and impressive history of measure development and validation. However, it is only recently that organized psychology has begun to move toward developing assessment systems or guidelines. For example, the Society for Pediatric Psychology launched an assessment initiative we describe in the next section, and the American Psychological Association just developed a database of measures that could be used in professional practice (Goodheart, 2011). This lag in promoting assessment principles, tools, and practices may simply be another example of organized psychology's apparent reluctance, relative to other health professions, to operationalize and promote practice guidelines and requirements. It is also, at least partially, due to the extremely limited attention to the foundational role that assessment activities play in evidence-based psychological services (cf. Cohen, La Greca, Blount, Kazak, Holmbeck, & Lemanek, 2008).

The *Standards for Educational and Psychological Testing* (American Educational Research Association, American Psychological Association, & National Council on Measurement in Education, 1999) set out generic standards to be followed in developing and using psychological instruments, but they offer no guidance on the level of psychometric adequacy an instrument should have. Psychometric characteristics are not properties of an instrument per se but, rather, are properties of an instrument when used for a specific purpose with a specific sample. Accordingly, assessment scholars, psychometricians, and test developers have typically been reluctant to set the minimum psychometric criteria necessary for specifying when an instrument is scientifically sound (cf. Streiner & Norman, 2003). Although understandable, this is of little aid to clinicians, who must make decisions about what assessment tools to use in their practices, how best to use and combine the various forms of information they obtain in their assessment, and how to integrate assessment activities into other necessary aspects of clinical service. Fortunately, some initial efforts have been made to operationalize the criteria necessary for designating psychological instruments and assessment processes as evidence-based. It is to these efforts that we now turn our attention.

## Evidence-based Assessment Initiatives and Criteria

In this section, we review three approaches to operationalize evidence-based psychological instruments.

As we will illustrate, these initiatives differed in the criteria used to identify best available instruments, the scope of the search strategies used to develop a pool of instruments to be evaluated, and the manner in which the criteria were systematically applied to the pool of instruments. As will become apparent, all three approaches have their strengths and limitations. However, one major limitation, at least for the promotion of EBP, is that all developed criteria for evidence-based *instruments*, not for evidence-based *assessments*. As we described previously in this chapter and elsewhere (Hunsley & Mash, 2007; Mash & Hunsley, 2005), this reflects the state of our (limited) scientific knowledge of the processes, outcomes, and utility of psychological assessments. Accordingly, it is perhaps more accurate to describe these three initiatives as focusing on evidence-based instruments (EBI) rather than EBA per se.

The first comprehensive effort to develop and apply criteria for evaluating clinical instruments of which we are aware is that of Bickman et al. (1999). As part of the Australian government's effort to reform mental health services, these researchers conducted a thorough review of outcome measures for use in child and adolescent mental health services. Based on their efforts, they recommended that a modular outcome measurement system be implemented in which brief, easily administered and interpreted measures are used in each of three assessment modules. These modules were focused on (a) background assessment (i.e., measuring factors in the youth and family's background that are likely to influence treatment), (b) baseline and follow-up assessment (i.e., measuring aspects of the youth's and family's mental health prior to treatment and at subsequent points in service delivery), and (c) concurrent assessment (i.e., monitoring key variables throughout the course of treatment).

Database searches were conducted to relevant articles, chapters, and books published in the period 1990–1998, and a list of 188 measures was extracted from these sources. All available published information was then obtained and reviewed for these measures. Each measure was then rated on the basis of 29 criteria, which are presented in Table 5.1. Although many of the criteria involved simple yes/no ratings or similar ratings (e.g., number of minutes to administer the test), they also developed specific criteria for determining specific levels of reliability and validity (such as unacceptable, barely acceptable, and highly acceptable). A detailed list of coding keys for each criterion is available in Bickman et al. (1999).

**Table 5.1 Bickman et al. (1999) criteria for rating outcome measures for use in child and adolescent mental health services**

| | |
|---|---|
| Cultural sensitivity: | Evidence of bias |
| | Cultural norms |
| | Used in Australia |
| Suitability: | Cost |
| | Time required |
| | Training required |
| | Degree/experience required to administer |
| | Reading level |
| | Computer software available |
| Reliability: | Test–retest reliability within a 2-week period |
| | Test–retest coefficient |
| | Internal consistency |
| | Cross-informant agreement |
| | Inter-rater agreement |
| Content validity: | Theory-based items |
| | Expert judgment used in item evaluation |
| | Respondent feedback used in item evaluation |
| | Factor analytic findings |
| Construct validity: | Convergent validity |
| | Divergent validity |
| | Social desirability |
| | Group differences |
| | Sensitivity/specificity |
| Norms: | Current norms available |
| | Number of normative samples |
| Developmental sensitivity: | Number of forms for specific age groups |
| | Age effects |
| | Norms across ages and/or age groups |

After this initial coding, the research group developed 18 evaluation requirements that were most relevant for their task of determining the best measures for a modular outcome measurement system. Among these 18, 5 were designated as being the most important: these were that the test took less than 10 minutes to complete, required less than 2 hours of training for the person administering and interpreting the test, required no specialized back-

ground for using the test, had evidence of convergent validity coefficients greater than .50, and had known groups validity. None of the 188 measures met all 18 requirements, but 10 measures met the reduced set of five requirements. To ensure full coverage of the necessary domains for the measurement system, additional measures were included that best satisfied the selection requirements, resulting in a battery of 31 measures.

There are several noteworthy aspects to the Bickman et al. work. They include the use of systematic search strategies to generate an initial list of tests to be evaluated, the use of appropriate and justifiable evaluation criteria (including both scientific and practice-relevant criteria), the presentation of specific requirements of psychometric adequacy, and the identification of key elements necessary for a test to be included in their measurement system. Of course, there are some limitations, the most notable being that (a) the sheer volume of work involved in their literature search and subsequent coding of criteria means that their approach to determining the best available measures cannot be easily implemented by psychologists reviewing the measures available for other assessment purposes and other client populations, and (b) the requirements set for their measurement system likely mean that their conclusions about the best available measures may not be applicable to other clinical psychology practice contexts.

The work presented in a recent volume by Hunsley and Mash (2008a) has some similarities to the Bickman et al. initiative, inasmuch as explicit criteria were used to evaluate the adequacy of psychological instruments. The scope of the Hunsley and Mash volume is, however, much broader, with measures used in the assessment of the most commonly encountered disorders or conditions among children, adolescents, adults, older adults, and couples (e.g., anxiety disorders, mood disorders, disruptive behavior disorders, sexual disorders, couple distress, sleep disorders, personality disorders, self-injurious thoughts and behaviors, substance-use disorders, pain). To ensure the clinical relevance of the review of EBIs, reviews by subject-area experts focused on three clinically important assessment purposes: diagnosis, case conceptualization and treatment planning, and treatment monitoring and evaluation. With these purposes in mind, subject-area experts focused on assessment measures and strategies that had either demonstrated their utility in clinical settings or have a substantial likelihood of being clinically useful. Thus, the measures reviewed

in the volume were selected to be among the best measures currently available. The experts considered the full range of relevant assessment methods (i.e., interviews, self-report, observation, performance tasks, computer-based methods, physiological, etc.), but considerations of scientific evidence and clinical feasibility were used to guide decisions about which instruments to review in detail. Some authors (e.g., Green, Worden, Menges, & McCrady, 2008) reported developing and following a systematic methodology for identifying possible measures for inclusion in their review. The ways in which age, gender, ethnicity, and other relevant patient characteristics influence both the assessment measures and the process of assessment for the disorder/condition were also examined.

Criteria developed by Hunsley and Mash (2008b) were used to evaluate all instruments reviewed in the volume. These criteria were explicitly designed to allow for the determination of measures that were "good enough" for clinical and research use. Rather than focusing on standards that defined ideal criteria for a measure, the intent was to have criteria that would indicate the minimum evidence sufficient to warrant the use of a measure for specific assessment purposes and clinical problems. In operationalizing the "good enough" principle, we developed specific rating criteria to be used across categories of psychometric properties that have clear clinical relevance.

The rating framework focused on nine criterion categories: norms, internal consistency, inter-rater reliability, test–retest reliability, content validity, construct validity, validity generalization, sensitivity to treatment change, and clinical utility. Each of these categories was examined in relation to a specific assessment purpose (e.g., case conceptualization and treatment planning) in the context of a specific disorder or clinical condition (e.g., eating disorders, obsessive-compulsive disorder, late life depression), and factors such as gender, ethnicity, and age were considered in making ratings within these categories. For each criterion category, a rating of less than adequate, adequate, good, excellent, unavailable, or not applicable was possible based upon the invited expert's appraisal of the preponderance of available evidence. The precise nature of what constituted adequate, good, and excellent varied from category to category. In general, a rating of adequate indicated that the instrument meets a minimal level of scientific rigor, good indicated that the instrument would generally be seen as possessing solid scientific support, and excellent indicated there was extensive, high-quality supporting evidence.

A rating of less than adequate indicated that the instrument did not meet the minimum level set out in the criteria. A rating of unavailable indicated that research on the psychometric property under consideration had not yet been conducted or published. A rating of not applicable indicated that the psychometric property under consideration was not relevant to the instrument (e.g., inter-rater reliability for a self-report symptom rating scale). Precise details about these specific criteria are presented in Tables 5.2 and 5.3.

On the basis of their evaluations, subject-area experts indicated instruments that are the best measures currently available to clinicians for specific purposes and disorders and, thus, are highly recommended for clinical use. Given the considerable differences in the state of the assessment literature for different disorders/conditions, there was some variability among experts in precisely operationalizing the rating of *highly recommended*. That being said, a moderate level of consistency in these ratings, at least, was ensured by the requirement that a highly recommended rating could only be considered for those instruments that had achieved ratings of good or excellent in the majority of their rated psychometric categories. Not surprisingly, there were more highly recommended instruments for the assessment of some disorders than for others. For example, in the assessment of schizophrenia, 2 assessment instruments were rated as highly recommended for diagnostic purposes, 12 for case conceptualization and treatment planning purposes, and 13 for treatment monitoring and outcome evaluation purposes (Mueser & Glynn, 2008). In contrast, for bipolar disorder, three instruments were identified as highly recommended for diagnosis, none for case conceptualization and treatment planning, and only 2 for treatment monitoring and outcome evaluation (Johnson, Miller, & Eisner, 2008).

The major strengths of the Hunsley and Mash (2008a) work include the use of subject-area experts to identify and rate assessment instruments, a focus on clinically meaningful assessment purposes, the presentation of specific requirements of psychometric adequacy, and the broad range of clinical conditions addressed in reviews of the assessment literature. Some of the limitations of this initiative are the flip side of the strengths. For example, the use of experts to select and rate instruments (rather than using systematic literature review strategies and independent coders) means that some solid instruments may have been overlooked and that the ratings of psychometric adequacy could have been affected by subjective

**Table 5.2  Hunsley and Mash (2008b) criteria for rating assessment instruments: Norms and reliability**

| NORMS |
| --- |
| *Adequate* = Measures of central tendency and distribution for the total score (and subscores if relevant) based on a large, relevant, clinical sample are available |
| *Good* = Measures of central tendency and distribution for the total score (and subscores if relevant) based on several large, relevant samples (must include data from both clinical and nonclinical samples) are available |
| *Excellent* = Measures of central tendency and distribution for the total score (and subscores if relevant) based on one or more large, *representative* samples (must include data from both clinical and nonclinical samples) are available |

| INTERNAL CONSISTENCY |
| --- |
| *Adequate* = Preponderance of evidence indicates alpha values of .70–.79 |
| *Good* = Preponderance of evidence indicates alpha values of .80–.89 |
| *Excellent* = Preponderance of evidence indicates alpha values ≥.90 |

| INTER-RATER RELIABILITY |
| --- |
| *Adequate* = Preponderance of evidence indicates κ values of .60–.74; the preponderance of evidence indicates Pearson correlation or intraclass correlation values of .70–.79 |
| *Good* = Preponderance of evidence indicates κ values of .75–.84; the preponderance of evidence indicates Pearson correlation or intraclass correlation values of .80–.89 |
| *Excellent* = Preponderance of evidence indicates κ values ≥.85; the preponderance of evidence indicates Pearson correlation or intraclass correlation values ≥.90 |

| TEST–RETEST RELIABILITY |
| --- |
| *Adequate* = Preponderance of evidence indicates test–retest correlations of at least .70 over a period of several days to several weeks |
| *Good* = Preponderance of evidence indicates test–retest correlations of at least .70 over a period of several months |
| *Excellent* = Preponderance of evidence indicates test–retest correlations of at least .70 over a period of a year or longer |

biases (including our own biases in inviting the contributors to the volume). Similarly, the focus on specific assessment purposes, although enhancing the clinical relevance of the assessment reviews, may have resulted in important and scientifically supported instruments not being represented (e.g., broadband measures such as the MMPI-2 and MMPI-A did not appear as highly recommended for any disorder/condition–assessment purpose combination). Finally, the overall ratings for some dimensions (e.g., clinical utility) were necessarily based on a smaller evidence base than those for other dimensions (e.g., reliability and validity).

A very different approach to classifying EBIs was taken in a recent task force initiative of the APA Society of Pediatric Psychology (Cohen et al., 2008). The task force steering committee and a set of expert working groups identified measures that fell into one of eight areas of broad interest: quality of life, family functioning, psychosocial functioning and psychopathology, social support and peer relations, treatment adherence, pain, stress and coping, and cognitive functioning. A survey that included all 367 instruments was posted on the Society's listserve, and an additional 56 measures were added to the list of measures to be considered for the designation of evidence-based. Work groups for each area were instructed to focus on reviewing the most widely used and researched instruments and to use a combination of the results of the survey, the current literature, and their own expertise in selecting instruments to be reviewed.

The criteria that were developed to determine whether an instrument was evidence-based were based on those used to identify empirically supported treatments. Thus, depending on the extent of the empirical support, any measure presented in the peer-reviewed literature could be designated as

**Table 5.3  Hunsley and Mash (2008b) criteria for rating assessment instruments: Validity and utility**

CONTENT VALIDITY

*Adequate* = The test developers clearly defined the domain of the construct being assessed and ensured that selected items were representative of the entire set of facets included in the domain.

*Good* = In addition to the criteria used for an Adequate rating, all elements of the instrument (e.g., instructions, items) were evaluated by judges (e.g., by experts, by pilot research participants).

*Excellent* = In addition to the criteria used for a Good rating, multiple groups of judges were employed and quantitative ratings were used by the judges.

CONSTRUCT VALIDITY

*Adequate* = Some independently replicated evidence of construct validity (e.g., predictive validity, concurrent validity, convergent and discriminant validity)

*Good* = Preponderance of independently replicated evidence, across multiple types of validity (e.g., predictive validity, concurrent validity, convergent and discriminant validity), is indicative of construct validity.

*Excellent* = In addition to the criteria used for a Good rating, evidence of incremental validity with respect to other clinical data

VALIDITY GENERALIZATION

*Adequate* = Some evidence supports the use of this instrument with either (a) more than one specific group (based on sociodemographic characteristics such as age, gender, and ethnicity) or (b) in multiple contexts (e.g., home, school, primary care setting, inpatient setting)

*Good* = Preponderance of evidence supports the use of this instrument with either (a) more than one specific group (based on sociodemographic characteristics such as age, gender, and ethnicity) or (b) in multiple settings (e.g., home, school, primary care setting, inpatient setting)

*Excellent* = Preponderance of evidence supports the use of this instrument with more than one specific group (based on sociodemographic characteristics such as age, gender, and ethnicity) *and* across multiple contexts (e.g., home, school, primary care setting, inpatient setting)

TREATMENT SENSITIVITY

*Adequate* = Some evidence of sensitivity to change over the course of treatment

*Good* = Preponderance of independently replicated evidence indicates sensitivity to change over the course of treatment

*Excellent* = In addition to the criteria used for a Good rating, evidence of sensitivity to change across different types of treatments

CLINICAL UTILITY

*Adequate* = Taking into account practical considerations (e.g., costs, ease of administration, availability of administration and scoring instructions, duration of assessment, availability of relevant cutoffs scores, acceptability to patients), the resulting assessment data are likely to be clinically useful.

*Good* = In addition to the criteria used for an Adequate rating, there is some published evidence that the use of the resulting assessment data confers a demonstrable clinical benefit (e.g., better treatment outcome, lower treatment attrition rates, greater patient satisfaction with services).

*Excellent* = In addition to the criteria used for an Adequate rating, there is *independently replicated* published evidence that the use of the resulting assessment data confers a demonstrable clinical benefit.

promising, approaching well-established, and well-established. The precise criteria are presented in Table 5.4. Along with these criteria, the work groups were asked to evaluate the clinical and research utility of the measures and to identify which measures could be used with various ethnic and linguistic minority populations.

The decision in the Society of Pediatric Psychology initiative to have an initial pool of possible EBIs generated by those working in the field of pediatric psychology ensures that the pool contained many measures that were both scientifically sound and clinically useful, although the lack of a systematic review strategy may have resulted in some relevant measures being overlooked. As with the Hunsley and Mash (2008a) effort, the use of subject-area experts has both strengths and weaknesses: It ensures that knowledgeable individuals were involved in examining possible EBIs, but subjective biases may have affected both the generation of the list of instruments to be considered and the manner in which criteria were applied. The choice of empirically supported treatment-like criteria was an interesting one. On the one hand, the consistency with treatment criteria provides a kind of face validity to the criteria; on the other hand, given that assessments can be undertaken for a range of purposes, the voluminous nature of the psychological assessment literature, and the psychometric sophistication evident in many assessment articles, these criteria may be both too nonspecific and too lax to provide a thorough and meaningful evaluation of an instrument's evidence base. For example, in the area of psychopathology and psychosocial functioning, which we use for comparison purposes in the next section, nearly all of the instruments reviewed were designated as evidence-based. Finally, although the

work groups were provided psychometric descriptions and references to guide their evaluations, the lack of precise requirements for what constitutes "good" validity and reliability limits the transparency of decisions made about psychometric adequacy.

## Evidence-based Instruments: Current Status and Issues

The three initiatives just described all attempted to apply standardized criteria for determining the extent and quality of the evidence base supporting psychological measures. Despite a common goal, the three differed substantially in the methods used for identifying and evaluating potential EBIs. Although the availability of multiple frameworks for methods and criteria is probably appropriate at this early juncture in the operationalization of EBA, it does raise questions about the comparability and validity of the various efforts. Do the three approaches simply provide different routes to the same outcome (i.e., do they all identify a similar set of EBIs?), or do they provide different routes *and* different outcomes (i.e., is there little consistency across frameworks in the instruments identified as evidence-based?)? If similar instruments are identified regardless of the framework used, then parsimony of methods and criteria should prevail in determining the best framework to use in subsequent work. However, if there is little overlap among instruments identified as evidence-based, then essential questions about what constitutes an EBI must be addressed.

To begin to answer these types of questions, we compared the results of the Society for Pediatric Psychology and the Hunsley and Mash (2008a) work. For both, measures of psychopathology and adjustment were examined for child and adolescent

---

**Table 5.4  Cohen et al. (2008) criteria for rating assessment instruments**

Well-established assessment
- Measure presented in two or more peer-reviewed articles by different investigators/investigatory teams
- Details about measure are available, thus allowing critical evaluation and replication
- Detailed information indicating good reliability and validity in at least one peer-reviewed article

Approaching well-established assessment
- Measure presented in two or more peer-reviewed articles, possibly by the same investigator/investigatory team
- Details about measure are available, thus allowing critical evaluation and replication
- Validity and reliability data are moderate, or information presented only in vague terms

Promising assessment
- Measure presented in at least one peer-reviewed article
- Details about measure are available, thus allowing critical evaluation and replication
- Validity and reliability data are moderate or information presented only in vague terms

populations. Although Bickman et al. (1999) also examined these types of instruments, the particular requirements for their initiative (e.g., brief administration time, no specialized background required for administering the instrument) generated a list of recommended instruments that was not directly comparable to those from the other two frameworks. Therefore, in Table 5.5, we present a list of instruments, including specific internalizing or externalizing problems and broadband measures of symptoms and adjustment, that received the highest ratings in the two evaluation systems. These measures were either rated as well-established by the psychosocial adjustment and psychopathology work group (Holmbeck et al., 2008; Table 5, column 1) or as evidence-based by the authors of chapters in Hunsley and Mash (2008a) that focused on youth-related disorders (Dougherty, Klein, Olino, & Laptook, 2008; Frick & McMahon, 2008; Johnston & Mah, 2008; Silverman & Ollendick, 2008; Table 5, column 2). Because of our focus on instruments to assess psychopathology, we did not include measures of self-esteem or self-perception rated by Holmbeck et al.

Table 5.5 clearly demonstrates that a wide range of measures are available for assessing youth psychopathology and psychosocial functioning. These include both measures assessing specific problems and more general symptom and adjustment measures. However, it is also apparent that the two frameworks used to determine generated lists of EBIs resulted in only modest overlap. Of the 26 psychopathology measures rated by Holmbeck et al. as well-established, only 16 were seen as sufficiently evidence-based to be included by the authors in the Hunsley and Mash volume. Likewise, of the 29 instruments rated as evidence-based by the Hunsley and Mash authors, only 16 were rated as well-established by Holmbeck et al. Clearly, not all roads lead to the same list of EBIs. The emphasis on a pediatric context in the Holmbeck et al. review, compared to an emphasis on a general clinical context in the other reviews, probably contributed to these discrepancies. However, the extent and nature of the discrepancies are such that we believe other factors played a contributing role in the differences observed in Table 5.5.

By examining the nature of the instruments listed in the table and the material provided by the authors whose reviews provided the information therein, it is evident that at least two main factors were responsible for the discrepancies between the two frameworks. First, the instruments identified by Holmbeck et al. were almost entirely self-report measures, whereas the Hunsley and Mash authors were more likely to include interview and observational methods in their set of recommended instruments. Second, many of the measures identified by Holmbeck et al., but not by authors in the Hunsley and Mash volume, were ones identified as commonly used *research* measures in the Society of Pediatric Psychology survey. Of course, differences in the number of required studies supporting each measure ("two or more" vs. "the preponderance of published evidence") and the precision of criteria for establishing psychometric adequacy may also have contributed to the discrepant outcome. This is especially likely as Holmbeck et al. reported that many of the instruments rated as well-established had psychometric weaknesses, such as a lack of full psychometric data on reliability and validity, poor internal consistency, limited content validity, inconsistent factor structure across studies, and high correlations with measures of social desirability. This also suggests that their criteria may, indeed, have been too general and too lenient. It is worth noting that, in reviewing a very different literature (anxiety measures used with older adults), Therrien and Hunsley (2013) recently came to essentially the same conclusion regarding the Society for Pediatric Psychology criteria.

In discussions of how to best operationalize EBAs or EBIs, it is worth noting that the evaluation frameworks described in the previous section all differ from the approach that is typically taken in evaluating services in evidence-based medicine (EBM). As discussed by Youngstrom (2008), it may be appropriate to consider explicitly adopting the evidence hierarchy approach used in EBM. In general, based largely on internal validity considerations, evidence hierarchies place expert opinion on the lowest level of the hierarchy, followed by case studies, group research designs that have shortcomings in addressing threats to internal validity, and group research designs that have a high degree of internal validity. At the top of the hierarchy are systematic reviews of well-designed studies (including meta-analyses). Clinicians searching the scientific literature to locate information that could aid service delivery efforts are explicitly encouraged to use the evidence hierarchy, turning to evidence at a lower level in the hierarchy only if the evidence at the highest available level is insufficient or not applicable to the situation at hand.

In reviewing the literature to develop an evidence hierarchy, two aspects are critical. First, a sys-

*Note:* For the Cohen et al. column, Yes indicates that an instrument was rated as well-established or approaching well-established, and No indicates that the instrument was not reviewed. For the Hunsley and Mash column, Yes indicates that an instrument was evaluated as evidence-based, and No means that the instrument was not reviewed.

tematic search of the peer-reviewed literature should be undertaken: Although this strategy was used by Bickman et al., neither the Society for Pediatric Psychology nor the Hunsley and Mash (2008a) initiatives used this strategy. Second, reliance on the best available evidence is encouraged (i.e., results from the highest level of the hierarchy). All three frameworks we reviewed encouraged this and attempted to operationalize this, albeit in different ways. This illustrates the fact that, although conceptually clear and straightforward, operationally defining steps in the evidence hierarchy is neither an obvious nor a simple task. Similarly, although it may be relatively easy to conduct a literature search for evidence about which treatments "work" for a disorder like agoraphobia, searching the literature on the assessment of agoraphobia is a much more complex task. For example, if a psychologist is searching for information on conducting assessments as part of the monitoring of treatment provision, the resulting literature will be substantially different than would be the case if the search was for the purpose of diagnosing agoraphobia. Therefore, although a systematic literature search strategy may be the optimal approach, the search will need to be sensitive to the specific purposes of the assessment task under consideration.

## Building a Truly Evidence-based Psychological Assessment

As we have indicated in the proceeding sections, some progress has been made in developing the foundation for EBA. Having discussed the question regarding appropriate criteria for EBIs, in this section we highlight some of the other issues that need to be addressed in order for psychological assessment to be truly evidence-based. These include the meaning of scores and change scores on psychological instruments, the role of incremental validity in optimizing assessment procedures, the need for evidence on clinical utility, the importance of moving beyond EBIs to consider how best to integrate data and make scientifically sound clinical decisions, and, finally, the relation between EBA and EBT.

## *The Meaningfulness of Instrument Metrics and Change Scores*

Unlike information about weight or height, scores on psychological instruments do not, of themselves, convey much information about a person's functioning (Blanton & Jaccard, 2006). Knowing that someone obtained a score of 20 tells us nothing unless we know the range of possible scores, norms for the instrument and, in the case of clinical instruments, the cut-score value(s) that indicate whether a score is in the "clinical" or "normal" range. Because of the diverse range of clients for which instruments may be used, it is critical that nationally representative norms be available that are sensitive to possible gender and age influences (Achenbach, 2005). Although clinical cutoffs are reported for many clinical instruments, either in a test manual or in the research literature, the manner in which the cut-scores were derived may be problematic (Meehl & Rosen, 1955). Specifically, using a cut-score derived from samples in which clinical cases are overrepresented compared to usual base rates will usually result in frequent classification errors (e.g., determining that a person scored in the clinical range of functioning when, in fact, the person's difficulties are not that extreme). The best solution is to use signal detection theory and receiver operating characteristic curves to operationalize multiple cut-scores that can take into account base rate information (e.g., McFall & Treat, 1999). Although such analyses are increasingly being used to derive clinical cutoffs, many instruments do not yet have cut-scores derived in this manner.

Just as a score itself usually has no intrinsic meaning, a change in a person's scores over time is also meaningless without a standardized way of interpreting the magnitude of the change. This is a key concern for clinical psychologists, as monitoring changes in functioning via self-report and observational instruments provides us with information about the impact of our treatments (cf. Kazdin, 2006). To this end, it is necessary to determine whether the observed change in scores is (a) more than simply a matter of measurement error and (b) substantial enough to indicate that improvement has occurred.

Such factors are considered in a set of statistics designed to evaluate clinically significant changes in scores (see Lambert, Hansen, & Bauer, 2008). For any instrument for which basic psychometric information is available, it is possible to derive a value to determine the minimum changes in scores necessary to indicate that a client is no longer functioning in the clinical range (for an example applied to the Beck Depression Inventory, see Seggar, Lambert, & Hansen, 2002).

### Incremental Validity and Evidence-based Assessment

Incremental validity addresses the question of whether data from an instrument (or other source of data) adds to the prediction of a criterion above what can be predicted by other sources of data (Hunsley & Meyer, 2003; Sechrest, 1963). Given the plethora of available clinical instruments, shockingly little information is available on the extent to which data from an instrument improves upon what can be obtained from simple sociodemographic characteristics or other psychological instruments. Evidence of incremental validity is important for a host of reasons, both conceptual (e.g., does an instrument measure a construct better than similar measures?) and practical (e.g., is it cost-efficient to obtain extensive assessment data from multiple informants?).

Clinical psychologists often gather data from multiple measures and multiple informants, yet there is little evidence in the empirical literature to aid in determining which measures to use, how to combine them, and what to do if conflicting results are obtained with some measures. Progress is being made in some areas. For example, Pelham, Fabiano, and Massetti (2005) reported that, in diagnosing attention-deficit/hyperactivity disorder in youth, structured diagnostic interviews do not possess incremental validity over rating scales and, therefore, are likely to have little value in clinical settings. More such research is necessary before clinical psychologists will be able to make scientifically informed decisions about which instruments to use in an assessment (and which may be redundant and cost *in*effective).

### Clinical Utility and Evidence-based Assessment

Evidence about enhancements to decisions made by clinicians and/or service outcomes experienced by patients are central aspects of clinical utility, regardless of whether the focus of the evidence is on diagnostic systems (e.g., First et al., 2004), psychological instruments (e.g., McFall, 2005), or inter-vention strategies (e.g., American Psychological Association Presidential Task Force on Evidence-Based Practice, 2006). Attention to clinical utility has grown in recent years but, unfortunately, there is still little evidence that bears on the question of the extent to which EBIs or EBA have clinical utility. For example, there is some evidence that functional analyses can have added value over other clinical data in some treatment contexts (Haynes, Leisen, & Blaine, 1997) and that the Outcome-Questionnaire-45 (OQ-45), a self-report measure of distress, interpersonal relations, and social functioning, has considerable clinical utility.

The OQ-45 research provides an excellent example that could be used in designing clinical utility studies for other instruments. Specifically, Lambert, Whipple, Hawkings, Vermeersch, Nielsen, and Smart (2003) conducted a meta-analysis of three utility studies in which more than 2,500 adult clients completed the instrument after each therapy session. Clinicians in the control condition did not receive information about the client scores; clinicians in the experimental condition received feedback about the scores that was limited to an indication of whether clients, based on normative data, were making adequate treatment gains, making less-than-adequate treatment gains, or experiencing so few benefits from treatment that they were at risk for negative treatment outcomes. By the end of treatment, based on OQ-45 data, 21% of clients in the control condition had experienced a deterioration of functioning and 21% had improved in their functioning. In the experimental condition, only 13% of clients had deteriorated and 35% had improved. Such results provide a very compelling indication of the clinical utility of the instrument.

### Integration of Data and Clinical Decision-making: From Evidence-based Instruments to Evidence-based Assessment

As we indicated early in this chapter, EBA must involve the recognition that psychological assessment is a complex decision-making task. Decisions must be made about which constructs to assess and which instruments should be used to assess these constructs. The data obtained from instruments must be then integrated and interpreted, and the impact of potential errors and biases in this process must be considered. However, as we have illustrated, reviews of EBAs to date to appear to be primarily lists of EBIs.

It is possible that this may simply reflect the early stage of development of EBA and that, over time,

increased attention will be paid to the pressing question of how data from EBIs can contribute to a truly evidence-based assessment. Although we know a great deal about how clinical decision-making can go wrong (Garb, 1998), we have only a limited sense of how results of nomothetic research can be used to guide the integration and interpretation of data for a specific patient (see, for example, Haynes, 2008; McGrath, 2008; and Persons, 2006). Important steps are being taken by researchers in a number of areas to develop assessment protocols that are evidence-based, straightforward to use, and provide feedback that minimizes the reliance on clinician interpretation of the data (e.g., Ebesutani, Bernstein, Chorpita, & Weisz, 2012; Jenkins, Youngstrom, Youngstrom, Feeny, & Findling, 2012). In the meantime, though, the most scientifically sound option available for many assessment tasks may be to ensure that assessments are conducted with EBIs in a manner that is informed by the research evidence regarding key constructs to assess for specific patient conditions and assessment purposes.

### The Relation between Evidence-based Assessment and Evidence-based Treatment

All EBPs rely on gathering data from different sources, integrating data, and making service decisions based on these data. As we have discussed, EBA and EBT are inextricably related, and most likely represent different parts of the same overall process. Whether a treatment is designated as evidence based in the first place depends on the quality of data used to evaluate its outcome. If these data are derived using flawed assessment instruments or processes, then designating a treatment as evidence-based has little meaning. In addition, since EBTs are designed for specific disorders and problems, their effective use requires that these disorders and problems be assessed using instruments and processes that are evidence-based for the purpose of identifying and diagnosing these problems. A failure at the level of assessment may very well lead to the inappropriate or ineffective use of EBT if a treatment is paired with a target problem for which it has not been evaluated (Weisz & Gray, 2008).

Despite recognition of the critical synergy between EBA and EBT, EBT continues to generate considerable attention, whereas EBA receives little to none. For example, a comprehensive 2008 Special Issue of the *Journal of Clinical Child and Adolescent Psychology* (Silverman & Hinshaw, 2008) on evidence-based psychosocial treatments for children and adolescents is virtually silent on the role of

assessment in EBT. This is so despite the fact that considerable attention was given to EBA in an earlier Special Section of the same journal (Mash & Hunsley, 2005). The operational rule here, and in other reviews of EBT, seems to be that the quality of outcome data underlying EBT recommendations is assumed to be high, despite evidence to the contrary. Moreover, we know very little about how assessments and the data they generate are being used in the context of EBT. The tacit acceptance of the status quo and the continuing use of many assessment instruments that are problematic and lacking in clinical utility is clearly a concern, but one that appears to be unrecognized. As pointed out by Kazdin (1988) such "unfelt problems are dangerous because they are likely to be neglected and ignored" (p. 9). Thus, despite progress on the psychotherapy front, research into evidence-based psychological assessment is characterized by a lack of clarity regarding the kinds of evidence needed to evaluate the utility of assessment methods and processes, and limited progress in the field. Hopefully, the beginning efforts to specify criteria for EBA that we have described in this chapter will begin to redress this problem.

### Conclusions

As outlined in this chapter, some important initial steps have been taken in establishing specific criteria for EBIs and in addressing the scope of issues that must be addressed if EBA is to develop. Some useful guidelines and lists of instruments are now available for clinical psychologists to apply in their assessment activities. That being said, with only limited consensus on how EBA should be operationalized and an assessment literature that is largely focused on providing evidence of only basic psychometric properties (i.e., not incremental validity, evidence of utility, or testing of decision-making models), there is much more work to be accomplished to develop EBA. In many ways, the current situation is reminiscent of Paul's (1967, p. 111) famous question about psychotherapy from over 40 years ago: "*What* treatment, by *whom*, is most effective for *this* individual, with *that* specific problem, and under *what* specific set of circumstances?" With respect to EBA, we must ask what assessment data, from which informant, is most valid and clinically useful for this individual, with these specific problems, and under what specific set of life circumstances. Given the obvious connection between clinical assessment and clinical treatment, answering the assessment question is a necessary step in fully answering the treatment question.

## Future Directions

From our perspective, the main issues outlined in this chapter that need to be addressed in future research efforts are (a) clarifying the meaning of scores and change scores on psychological instruments, (b) increasing the role of incremental validity in optimizing assessment procedures, (c) developing the evidence base for the clinical utility of psychological instruments, and (d) developing a consensus about what constitutes EBA and, therefore, which set of criteria, guidelines, parameters, or list of assessment instruments a professional clinician should use as a reference for assessment activities.

There are, however, a number of other important issues that must be addressed in order to develop a truly evidence-based approach to psychological assessment. First, although there is much information on EBIs, we know very little about the assessment process in the context of clinical decision making. Thus, even when instruments are reliable and valid, the ways in which they are used in clinical practice may not be. There is clearly a need to move beyond EBIs, to consider how best to integrate data and make scientifically sound clinical decisions. Second, the content and procedures of usual psychological assessment practices are not well known. Usual assessment practices have typically been assessed via surveys that provide information about the percentage of clinicians using particular assessment instruments. However, such surveys tell us little about how assessment instruments are being used and integrated into clinical decision making. Despite longstanding recognition of a lack of knowledge in this area, our understanding remains quite limited. Recent studies of clinician attitudes toward the use of standardized assessment instruments may help to understand and overcome some of the barriers to using evidence-based assessments (Jensen-Doss & Hawley, 2010).

Third, as we have discussed, the relation between EBA and EBT involves much more than simply matching a valid diagnosis and selecting a designated EBT for this problem. Evidence should be used to guide both the assessment and treatment process from identifying and diagnosing a target problem, monitoring treatment progress and outcomes in relation to an EBT, and making ongoing adjustments in treatment procedures as needed. Weisz, Chu, and Polo (2004) have noted how the dialectic of assess→treat→reassess→adjust treatment→reassess is not well articulated in relation to current clinical practice. Operationalizing how this process is to proceed presents a major challenge for evidence-based health practices. Finally, the dissemination of EBTs also requires the dissemination of EBAs. This poses a problem, as we don't yet have an agreed-upon list of EBAs. Although the current list of instruments that appear in the sources cited in this chapter would be a good starting point, many recommended instruments (e.g., structured diagnostic interviews) are lengthy and complex to administer, thus making them difficult to use in clinical practice. On the other hand, more practice-feasible instruments may not provide the information needed to meet service system requirements (e.g., DSM diagnosis).

# Schools of Psychotherapy and the Beginnings of a Scientific Approach

James F. Boswell, Brian A. Sharpless, Leslie S. Greenberg, Laurie Heatherington, Jonathan D. Huppert, Jacques P. Barber, Marvin R. Goldfried, *and* Louis G. Castonguay

### Abstract

The theoretical, clinical, and empirical foundations of psychotherapy come from five primary movements that still exist today, continue to evolve, and remain scientifically productive: psychodynamic, cognitive-behavioral, humanistic, systemic, and integrative. The goal of this chapter is to examine the philosophical, clinical, and scientific underpinnings of each of these major traditions in detail. Experts in these five approaches will describe (a) the model of psychopathology (especially focusing upon etiological and maintenance factors emphasized in assessment and case formulation); (b) the focus and specific techniques used in treatment planning and implementation; (c) the hypothesized therapeutic mechanisms of change; and (d) the outcome literature/empirical support for each modality. We conclude with a look toward the future of the science of psychotherapy and the scientist-practitioner model of psychotherapy.

**Key Words:** Cognitive-behavioral therapy, humanistic therapy, integrative therapy, psychodynamic therapy, psychotherapy, systemic therapy

If defined as a "talking cure," psychotherapy has a very long history. The moral therapy that Pinel developed in the 18th century included not only the unchaining of patients (as it is often portrayed in undergraduate abnormal psychology textbooks) but also involved establishing safe and comforting relationships at both a personal and institutional level. As part of their therapeutic responsibilities, staff members of the asylums were asked to walk with, listen to, and talk with patients, with the ultimate goal of helping them find solace from the social afflictions that were believed to be partly responsible for their mental conditions. A similar philosophy toward mental disorders can be traced back to ancient Greece, where temples were created to help individuals restore a balance in what Hippocrates designated the major bodily "humors." In addition to the prescription of rest and music, the restorative treatments might well have involved meaningful (and hopefully soothing) verbal exchanges, if only as

a reflection of Hippocrates' belief that an intimate relationship between patient and healer was important to health. Arguably, however, the foundation of modern talking cures resides in Breuer and Freud's (1893) cathartic method, where successful treatment was assumed to require three conditions: (1) the patient remembering the traumatic event at the origin of his or her symptoms; (2) the patient re-experiencing the emotions felt during this traumatic event; and (3) the patient expressing both the event and emotional experiences to the therapist (Nisole, 1977). These three conditions, interestingly, are very consistent with today's leading treatment (exposure therapy) for post-traumatic stress disorder.

Although the cathartic method is no longer used (at least as originally prescribed by Freud and Breuer), it directly led to Freud's development of psychoanalysis proper. Although still practiced today, Freud's classical psychoanalysis did not

remain static but also spurred the development of several other important treatment approaches that are linked by a common goal of uncovering and understanding the (often unconscious) conflicts and early developmental experiences associated with the client's symptoms.

However, as early as the 1920s, opposition to psychoanalytic thinking and methods also served to galvanize the beginning of a second major tradition or school of therapy. Born in laboratories and intimately linked with animal research (e.g., Pavlov's and Seligman's dogs, Watson's rats, Skinner's pigeons, and Wolpe's cats), behavioral and later cognitive-behavioral approaches represented an effort to understand and treat abnormal behavior that used techniques based on the implementation of methods derived from the physical sciences.

With the 1950s came the genesis of another movement, often called the "third force" in psychology. It was in large part a reaction to several of the deterministic assumptions shared by psychodynamic and behavioral orientations. Rejecting the notion that human behaviors could be fully understood as the result of past learning or developmental conflicts, scholars and clinicians associated with humanistic, existential, and experiential traditions constructed models and therapeutic interventions focused on notions of emotional awareness, the creation of meaning, a person's capacity for choice, and human tendencies toward healthy growth and the actualization of potential.

A fourth movement was born in the late 1960s and early 1970s. This group of systemic and family-centered approaches emphasized the many complex and subtle interpersonal processes that shape and control human behaviors at least as much as (if not more than) the intrapersonal forces (e.g., intrapsychic conflict, classical and operant conditioning, actualization of potentialities) at the core of the previous three traditions.

As discussed here, these four movements still exist today, continue to evolve, and remain both theoretically and empirically productive. As it seems clear that many, if not most, of currently available forms of therapy can be linked in some way to these four traditions, the goal of this chapter is to examine them in detail. Experts in these four approaches will describe: the model of psychopathology (especially focusing upon etiological and maintenance factors emphasized in assessment and case formulation); the focus and specific techniques used in treatment planning and implementation; the hypothesized therapeutic mechanisms of change;

and the outcome literature and empirical support for each modality.[1]

Although we believe that each of these major approaches to psychotherapy is here to stay, it is also clear that the majority of practicing psychotherapists (at least in the United States) define themselves as eclectic or integrative (Norcross, 2005). As an attempt to improve psychotherapy based on points of convergences and complementarities between different schools, the integration movement has been described as a Zeitgest (Lecomte, 1987) in the literature. In our effort to provide a complete (as much as possible) picture of the contemporary landscape of psychotherapy, this chapter will offer a brief history of the integration movement, as well as a description of its current trends and empirical contributions.

As a way to further establish the scientific foundation of psychotherapy, the chapter will end with a plea for more research on the process and outcome of current approaches (including the integrative movement), as well as on principles of change that cut across most of them. It will also be argued that the future growth of the Scientist-Practitioner model underlying modern psychotherapy will likely benefit from research conducted with active collaborations between researchers and clinicians (also see Castonguay, 2011).

## Psychodynamic Approach

"Psychodynamic therapy" is a broad term used to encompass the many approaches for fostering understanding and alleviating human suffering that were directly influenced by Sigmund Freud, the intellectual father of psychodynamic therapy. Like all children, Freud's progeny have made choices that, although individual and autonomous, are nonetheless reflective of his influence. Some have decided to adhere closely to Freud's original formulations, others intensively focused upon one or more aspects, and several reacted against core principles while retaining others. This rich heterogeneity eventuated in a multitude of approaches with which therapists can flexibly

---

[1] The section on the psychodynamic approach was written by Brian A. Sharpless and Jacques P. Barber. The section on the cognitive-behavioral approach was written by Jonathan D. Huppert. The section on the humanistic approach was written by Leslie S. Greenberg. The section on the systemic approach was written by Laurie Heatherington. The section on psychotherapy integration was written by James Boswell, Louis Castonguay, and Marvin Goldfried.

treat the vicissitudes of human psychopathology, but also had the unintended consequence of making it particularly difficult to summarize across modalities without gross oversimplification or error. While acknowledging this risk, we will attempt to broadly describe the current state of the field. Prior to discussing specific content, it will be helpful to cast this modality in sharper relief by briefly describing what some have termed the psychodynamic "sensibility" (e.g., McWilliams, 2004).

This sensibility has many components. Psychodynamic therapists could be described as operating under a "hermeneutic of suspicion" (Ricoeur, 1970). Specifically, the superficial or manifest contents of speech, actions, and symptoms are often not taken at face value, but are instead openly questioned in the hope of revealing other meanings/values that may have been lost, disavowed, or never fully considered. Such meanings (although somewhat hidden) are nevertheless thought to possess relevance for, and impact on, the patient's present life, level of distress, and understandings of self and other. A corollary of this is a belief in, and overriding respect for, the complexity of human thought, action, emotion, and behavior in all of its many varieties and shades. This can be seen in Wäelder's (1936) concepts of "over-determination" (i.e., the belief that every mental event has many causes) and "multiple function" (i.e., that every action/symptom intended to solve one psychological conflict or problem is simultaneously an attempt to solve other problems). Further, understanding oneself and increasing freedom from the many determinisms present in life requires a high level of honesty and self-exploration (for both patient and therapist). What is *not* said can be as important as what is, and therapists strive to attend to the multiple levels of verbal and nonverbal communication; for, as Freud wrote in 1905, "betrayal oozes out of… every pore." Finally, the dynamic sensibility could also be characterized by a profound recognition of the human psyche's fragility. Namely, no one is immune from falling ill, psychopathology exists on a continuum (and in normal life), and we are all more vulnerable than we think. This can clearly be seen in dynamic therapy's proposed etiologies.

### Models of Function and Dysfunction

Although psychodynamic theories of pathology can diverge markedly, they are unanimous in viewing both psychopathology and health in developmental terms. This emphasis on the formative role of early experiences in current functioning is evident in two of the main psychodynamic subtypes. For instance, traditional drive and ego psychologists typically conceptualize patients in terms of psychosexual development and conflict. Early experiences influence and shape characteristic conflicts between sexual and aggressive wishes/impulses, external reality, and internalized societal prohibitions. As a result, certain *compromises* between these conflicts arise, some of which are maladaptive (e.g., depressive symptoms), as a means of attempting to cope with them. In contrast, healthier individuals who have successfully passed developmental challenges, or who have undergone psychotherapy, presumably possess more effective compromises (i.e., they are regulated by more developmentally mature defenses, such as the sublimation of aggressive urges) that elicit minimal anxiety. Thus, these individuals may be more flexible and better able to satisfy their needs using multiple adaptive behaviors.

Another important school of dynamic thought has been termed the *object relational approach*. Object relation theorists, influenced by Klein, Winnicott, and Fairbairn, believe that *relationships* (especially early ones) constitute the building blocks of both our character and our adult relational patterns. This shift away from emphasizing the primacy of sexual and aggressive drives and toward relationships (and relatedness itself) represented a significant theoretical modification from both classical psychoanalysis and ego psychology. *Objects* (an unfortunate choice of words meaning "that to which a subject relates"—usually other people) are internalized (i.e., psychically "taken in") over the course of human development. If a person does not have "good enough" caregivers who adequately meet his or her physical and emotional needs, and therefore does not have opportunities to internalize *adaptive* objects, a future of interpersonal conflicts and an inability to maintain psychic homeostasis is often, but not always, the result (e.g., the borderline conditions). Further, inordinate levels of either dependence or independence in relationships (instead of healthy adult interdependent mutuality and respect) can also be a sequela.

Psychopathology viewed in object relational terms is a necessary adaptation to deficient environmental, innate, and interpersonal conditions. In contrast, the achievement of both a stable identity and object constancy (i.e., the capacity to tolerate loving and hostile feelings for the same person, view people as unique, and not use others instrumentally) is indicative of healthy object relations. The environment, one's biology, and one's parents need not be perfect, of course, but must allow for the

healthy development of these more nuanced views of self and other. Further, the work of therapy (and the therapeutic relationship itself) can move individuals toward healthier functioning. In ending this section, it is important to note that, in spite of all dynamic theories' emphasis on early development, they all seriously consider genetic and temperamental contributions to the development of psychopathology.

In line with the diversity and complexity of factors involved in dynamic models of health and psychopathology, the assessment process is a multilayered one. Although some therapists decry the use of the predominant nosological systems (i.e., DSM-IV-TR and ICD-10), many find it very important to possess an accurate and complete symptom topography. However, most dynamic therapists do not find these phenomenological descriptions sufficient in isolation, and they are usually supplemented with additional assessments. For instance, therapists try to understand their patient's character structure (i.e., neurotic, borderline, or psychotic), developmental and interpersonal histories, characteristic expressions (and non-expressions) of affect, and coping styles (e.g., defenses).

In addition, dynamic therapists attempt to listen to three complementary levels of discourse/communication. First, they try to be "objective" and realistic observers of their patients and their problems without being clouded by personal reactions, prejudgments, or preferences. Second, dynamic therapists attempt to fully *resonate* with their patients' idiosyncratic experiences. It is held to be of the utmost importance to understand (and subjectively capture) events in the world as they are colored through their patients' eyes. Third, the therapist's own idiosyncratic human reactions to the patient's experiences must be closely attended to. This not only provides crucial information about how others likely react to the patient, but also may serve to circumvent certain interpersonal "pulls" that may be less than therapeutic. The combination of these three different levels of communication (and the corresponding tension between subjective–objective and participant–observer) allows the therapist to triangulate relevant problem areas. Data derived from observations at these three levels also lend focus to the complex process of psychodynamic psychotherapy.

## The Process of Therapy

### TARGETS OF DYNAMIC PSYCHOTHERAPY

In a quote attributed to Freud (but not found in his corpus) it is stated that the capacity to love and work are indicators of mental health and, therefore, preeminent targets of treatment (Erikson, 1963). These goals possess a commonsense and intuitive appeal, and further seem to converge with the *realistic* worldview of the psychodynamic therapies.

This willingness to realistically interpret oneself and the world with neither "rose-colored" nor "dark-colored" glasses pervades several other targets of therapy. For instance, attaining a realistic sense of self and other is a principal focus of many dynamic approaches (e.g., object relational and self psychologies). This necessarily entails a recognition (and possibly acceptance) of traits and qualities that may be unattractive or unflattering, yet nonetheless real. Relatedly, helping to instill a sense of realistic hope for patients is also important, as is an acceptance of the many determinants in life (e.g., including much of what would fall under Heidegger's concept of "thrownness," or the fact that we exist, that we exist in a particular time, that we have particular parents or, put another way, that we were "thrown" into a world not of our choosing). We would argue that the acceptance of that which cannot be changed and an ability to take pride and enjoyment in who and what one is are both strong indicators of psychological health. Further, these factors are also conducive to the attainment of authentic senses of meaning and purpose.

Along with these somewhat more abstract targets, dynamic therapies also share clinical goals with other modalities. Symptom relief is often emphasized, especially in short-term psychodynamic psychotherapies (e.g., Milrod, Busch, Copper, & Shapiro, 1997), where longer-term goals (e.g., significant personality modification) may be inappropriate or unrealistic. Dynamic therapies also assist patients in freeing themselves from repetitive patterns (interpersonal or otherwise) that inevitably only lead to despair, pain, and thwarted potential. As with behavior therapy, there is a desire to help patients adapt to their particular environmental demands and contingencies. And, as is probably universal among the many talk therapies, there is a general belief that flexibility is good and rigidity is undesirable.

### THERAPIST TECHNIQUES AND THE EMERGENT PROPERTIES IN THERAPY

Most interventions contained in the armamentarium of dynamic therapists (e.g., see Thoma & Kachele, 1994) can be roughly divided into expressive and supportive techniques (Luborsky, 1984); the former focuses on uncovering relevant clinical material, as well as in increasing self-understanding and self-attunement. Expressive techniques are

epitomized by "interpretations," in which observable thoughts, feelings, or behaviors are directly linked to the dynamic content that are assumed to give rise to them. It is important to note that expressive techniques are not merely arid intellectual exercises, but must take place with affective urgency (and relatedness) in order to be effective.

In contrast, supportive techniques are intended to bolster and support adaptive defenses, shore up ego boundaries, make the patient feel more comfortable and more accepting of themselves, and facilitate the development of a positive therapeutic alliance. Some authors also consider interventions to be supportive if they facilitate the therapeutic process itself and enable patients to "open up." However, supportive techniques do not lead to or encourage regression, but instead are typically intended to combat immediate distress and return patients to their level of baseline functioning.

We term the many subtle forms of interaction arising between patient and therapist "emergent properties." This would include constructs such as the therapeutic alliance, transferences, countertransferences, and the "real" relationship. The therapeutic alliance has received much discussion (e.g., Hatcher & Barends, 2006), and will not be described further here. The current status of key dynamic constructs as transference (the attributing of qualities from earlier life relationships/experiences onto the therapist) and countertransference (the therapist's subjective experiences that are triggered by patient material) differ in some significant ways from Freud's original formulations, and definitions remain both in flux and hotly contested. In general, though, whereas transference was once seen as primarily a contributor of grist for the analytic mill, it has been increasingly viewed as important on its own terms, due to its many relational implications. Further, countertransference has ceased being viewed as merely a negative indicator of unresolved therapist issues, and is more often seen as an important font of clinical information in its own right. Finally, there is the "real" relationship, which has typically been considered how patient and therapist relate on their own terms and not as "parent substitute or working partner" (de Jonghe, Rijnierse, & Janssen, 1991, p. 696). It is important to note, however, that these various distinctions between relational constructs may not be as clear cut as they seem, for a therapist's "real" character traits may serve as "hooks" upon which they can more plausibly hang their transference reactions (e.g., an obese therapist may engender particular transferences, Baudry, 1991). Further, all

of these may have a direct (e.g., alliance) or indirect (e.g., interpretation of the transference leading to self-understanding) impact on outcome.

Taken together, the application of expressive and supportive techniques in a judicious manner (taking into account the idiosyncratic character, context, and strengths of the patient), when utilized in conjunction with the above-mentioned emergent properties, all join together to set the stage for work toward dynamic targets. However, we have yet to discuss the various therapeutic actions that may mediate dynamic therapy outcome.

THERAPEUTIC ACTIONS

Although therapeutic actions have been discussed in the literature, and several edited volumes on the topic exist (e.g., Lifson, 1996), empirical work and evidence have significantly lagged behind theory. We group therapeutic actions into increases in self-understanding (SU) and the attainment of corrective emotional experiences (CEE).

We have found it useful to conceptually subdivide "global" SU into specific subtypes, and we will briefly describe five of them here. First, the exploration of conflicts (both intrapersonal and interpersonal) is considered to be a core focus of dynamic therapy leading to greater self-understanding and positive outcome. Second, a patient's characteristic defense mechanisms or "character armor" (Reich, 1933) are held to be expressions of these very same unconscious conflicts, motivations, and desires. And, consonant with classical psychoanalysis, understanding and changing defenses are primary foci in psychodynamic therapy. Third, the exploration of a patient's object relations and capacity for object relatedness is thought to increase self-understanding, as well as contribute to therapy outcome. This often takes place in the context of the transference. Fourth, therapists who adopt a more hermeneutic approach to therapy look to narrative change as a means for increasing SU. In this, self/life-narratives are explored (and often co-written) in order to make them more coherent, comprehensible, nuanced, and capable of reflecting and encompassing the many complexities of lived human experience. A greater understanding of self and other is thought to result. Finally, reflective functioning is also related to SU. Reflective functioning, also termed *mentalization* (Fonagy, 2002), is the capacity to understand the behavior of oneself (and others) in terms of internal mental states (i.e., beliefs, thoughts, and emotions).

Corrective emotional experiences, or "reexperiencing the old, unsettled conflict but with a new

ending" (Bridges, 2006, p. 551) may be another important therapeutic action. As one prototypical example of a CEE, a patient becomes angry with the therapist and holds the expectation that the therapist (like others) will respond to anger with rejection and more anger. However, the therapist's different-than-expected responses to anger (e.g., curiosity and empathy) provides the patient with a novel experience that holds the potential to modify rigid schemas, foster interpersonal flexibility, and even (if powerful enough) modify psychic structure. Whereas some early theorists toyed with directly influencing the therapeutic environment in order to elicit these experiences (e.g., Alexander & French, 1946), most today would view CEEs more broadly and less manipulatively. Corrective emotional experiences can occur without the therapist necessarily deviating from "normal" dynamic therapy protocol. In this conception of CEEs, the empathic mode of non-judgmental listening, interpersonal reliability, and therapeutic structure can provide patients with reparative experiences. Further, the very act of feeling understood and accepted by another can elicit profound changes, as can the presence of an important individual in one's life who acts in ways (as just described) that do not "fit the pattern" one expects.

## Empirical Support

Whereas other schools of therapy (e.g., behavior therapy) developed hand-in-hand with an empirical and experimental approach, dynamic therapy arose from within a different methodological tradition. Historically, psychodynamic research focused primarily upon the intensive study of individual patients (i.e., the case study) instead of large-scale trials. The latter were likely hindered by a popular belief that dynamic therapy could not really be accurately studied because any operationalization of dynamic constructs into therapy manuals (a prerequisite for clinical trials) ineluctably made them enervated and sterile. There was also a widespread belief that existing measures of patient change were inadequate to capture dynamic change. However, several researchers began exploring the efficacy and mechanisms of dynamic treatments in the 1970s (e.g., Malan, Luborsky, and Strupp, to name a few).

In fact, evidence for the effectiveness of different forms of dynamic therapy exists. In longer dynamic treatments, evidence is consistent with the idea that lengthier and more intensive (e.g., Sandell, Blomberg, & Lazar, 1997) treatments evince better outcomes. With regard to short-term approaches, meta-analyses indicate that dynamic therapy is as effective as cognitive-behavioral therapy in treating Axis I and personality disorders (Liechsenring & Leibing, 2003; Leichsenring, Rabung, & Leibing, 2004). Although these findings are supportive of the effectiveness of dynamic therapy and the fact that it is at least equivalent to other approaches, additional research is needed, especially using the methodology of randomized clinical trials in order to compare it to well-established therapies for clearly defined disorders.

In addition to outcome literature and research into *general* processes of therapy that may exist *across* modalities (e.g., the therapeutic alliance, a construct also shown to have a causal role in patients' improvement in dynamic therapy [Barber, Connolly, Crits-Christoph, Gladis, & Siqueland, 2000]), several *dynamic-specific* constructs and therapeutic actions have received empirical attention and support, and three will be discussed here. First, dynamic interpretations have been found to be generally beneficial (Orlinsky, Rønnestad, & Willutzki 2004) and, more specifically, accurate and appropriate interpretations are associated with outcome (e.g., Crits-Christoph, Cooper, & Luborsky, 1988). However, this relationship between interpretations and outcome may be moderated by a patient's quality of object relations, although the direction of the relationship is unclear (e.g., Connolly et al., 1999; Hoglend et al. 2006). Second, dynamic therapy has been found to improve adaptive defensive functioning (e.g., Hersoug, Sexton, & Høglend, 2002), and these changes are also associated with outcome (e.g., Coleman, 2005). Interestingly, one study demonstrated that treatment continued past symptom recovery led to a normalization of defenses (Akkerman, Lewin, & Carr, 1999). Third, Levy et al. (2006) have shown that one year of expressive dynamic therapy (but not supportive dynamic therapy or dialectical behavior therapy) was associated with significant increases in reflective functioning in patients with severe personality disorders. These and other findings are promising, but additional elucidation of dynamic constructs (and their complex relation to outcome) is needed.

In closing, although high-quality research into dynamic therapy has begun, many more questions than answers remain, and certain core constructs (e.g., narcissistic vulnerabilities, internalization of the therapist as an object) have yet to be rigorously evaluated. However, it is heartening that many scholars have worked to operationalize their concepts and manualize their therapies (see Table 6.1 for examples). This makes it possible to both reliably

**Table 6.1  Examples of Psychodynamic Treatment Guides/Manuals for Specific Disorders**

| Source | Disorder | Source | Disorder |
|---|---|---|---|
| Busch et al. (2004) | Depression | Milrod et al. (1997) | Panic disorder |
| Luborsky et al. (1995) | Depression | Leichsenring et al. (2007) | Social phobia |
| Crits-Christoph et al. (1995) | Generalized anxiety disorder | Yeomans et al. (2002) | Borderline personality disorder |

train new psychodynamic therapists and adequately replicate empirical findings.

## Cognitive-Behavioral Approach

Cognitive-behavioral therapy (CBT) is probably better called *cognitive and behavioral therapies*, given that many treatments and traditions fall under the rubric of CBT. These therapies emphasize different theories or integrations of theories (e.g., cognitive vs. behavioral). Historically, behavior therapy developed out of the learning theory traditions of Pavlov (1927) and Skinner (1953), both of whom considered animal models of learning and their implications for psychopathology. More direct examinations of behavioral principles as applied to clinical theory were first developed by Mowrer (1939), Watson and Rayner (1920), and later by Wolpe (1952) and many others. The integration of notions of cognitive concepts with behavior therapy included work by Beck (1976), Ellis (1962), Goldfried and Davison (1976), and Meichenbaum (1977) in the 1960s and '70s.

From its outset, cognitive therapy was built on principles included in behavior therapy (see Beck, 1976), but with a focus on using such principles to facilitate the modification of cognitive distortions that were proposed to be the primary factor involved in the maintenance of depressive and other symptoms. In the last 30 years, significant progress has been made in understanding the cognitive and behavioral maintenance factors related to psychopathology in general (Harvey, Watkins, Mansell, & Shafran, 2004), and specific disorders in particular (e.g., Clark & Wells, 1995; Dalgeish, 2004; Mathews & Mackintosh, 1998; Mogg & Bradley, 1998), although there is still much to understand. In addition to the increased sophistication and empirical study of behavioral and cognitive mechanisms involved in psychopathology, an increasing emphasis has been placed on emotion as an important construct within these theories (Barlow, 2002; Power & Dalgleish, 1997; Samoilov & Goldfried, 2000; Teasdale & Barnard, 1993). In line with these and other recent developments, the

current status of CBT theories can be viewed as an integrative approach, considering cognitive, behavioral, emotional, and interpersonal factors in treatment, as well as biological issues. The advances in treatments will be described further here.

### Models of Function and Dysfunction

The basic tenets of CBT theory of human functioning and mental illness is that psychopathology is comprised of maladaptive associations among thoughts, behaviors, and emotions that are maintained by cognitive (attention, interpretation, memory) and behavioral processes (avoidance, reinforcement, etc.). Within CBT theories, there are different emphases on aspects of the characteristics of psychopathology and their maintenance mechanisms (e.g., Beck, 1996; Brewin, 2006; Foa, Huppert, & Cahill, 2006; Mineka & Zinbarg, 2006; Teasdale & Barnard, 1993). In general, CBT theories are stronger in their hypotheses regarding maintenance than etiology, and most interventions are aimed at interrupting or modifying cognitive, behavioral, emotional, and physiological processes and/or altering pathological beliefs, emotions, and behaviors that are involved in the maintenance of maladaptive or problematic behaviors.

It is beyond the scope of the current chapter to describe all of the various CBT theories of pathology and treatment in detail (some of these are books in and of themselves; e.g., Barlow, 2002; Power & Dalgleish, 1997). Instead, the common intersections of most of these theories will be described, with some examples from various theories used to illustrate the principles. Early behavioral theories suggested that associations between stimuli (S–S relationships) and between stimuli and responses (S–R relationships) led to learning maladaptive behaviors that underlie psychopathology (Mowrer, 1939; Watson & Raynor, 1920). Early cognitive theories proposed that idiosyncratic negative cognitive schemas underlay the cognitive, behavioral, and physiological symptoms of depression and other pathology (Beck, 1976).

Interventions that targeted both dysfunctional interpretations and predictions, as well as underlying beliefs (schemas) would therefore alleviate such pathology. Theories have expanded on the early cognitive and behavioral theories to create idiographic cognitive models for most disorders of psychopathology (Clark, 1986; Clark & Wells, 1995; Ehlers & Clark, 2000; Fairburn, Cooper, & Shafran, 2003; Salkovsksis, 1999; Rapee & Heimberg, 1997, etc.). Each of these models attempt to explain the core symptoms of specific disorders by developing a model of interacting cognitions, behaviors, and physiological responses that are maintained through lower- and higher-level cognitive processes including attention, interpretation, memory, and appraisal processes.

Cognitive and behavioral theories were not only integrated, but cognitive theories were also developed to explain many behavioral models of psychopathology, including the revised helplessness model of depression (Abramson, Seligman, & Teasdale, 1978) and emotional processing theories of anxiety and habituation (Foa & Kozak, 1986). The helplessness model of depression suggested that attribution of negative events to personal, permanent, and pervasive factors maintains depressogenic beliefs and may account for the depressive states caused by inescapable aversive situations, as described in the original behavioral account of learned helplessness (Abramson et al., 1978). Emotional processing theory (Foa & Kozak, 1986) followed Lang (1977) by suggesting that fear structures are propositional networks that contain information about stimuli; verbal, behavioral, and physiological responses; and the meaning of the stimuli and responses. Further, Foa and Kozak (1986) proposed that, for modification of a fear structure to occur, there are two necessary components: activation of the fear structure and incorporation of new, disconfirmatory information into the fear structure. Thus, cognitive processes were proposed to account for both within- and between-session habituation. Similarly, Barlow (1988) integrated cognitive appraisals of control and predictability into Gray's biobehavioral emotion theory account of anxiety to advance theory and treatment. These types of theorizing helped to create a dominance of cognitive theory within CBT, acquiring significant empirical support as well as clinical utility in advancing treatments.

In the last two decades, these theories have been expanded upon and refined based on accumulating evidence (Barlow, Sauer-Zavala, Carl, Ellard, & Bullis, under review). Some of these theories have undergone significant revision to accommodate new findings (Abramson, Metalsky, & Alloy, 1989),

while others have worked on updating the theories without a complete revision (Barlow, 2002; Beck, 1996; Foa et al., 2006). Many of these updates include the incorporation of recent information regarding the nature of the same processes that were originally discussed, such as learning, memory, attention, and extinction, as well as the advancement of newer findings regarding emotion regulation and similar constructs (Campbell-Sills, Barlow, Brown, & Hofmann, 2006; Gross, 1998). Some newer theories have focused specifically on the accumulation of information on competing information in memory (e.g., Brewin, 2006), while others have attempted to understand psychopathology in terms of multiple levels of information processing that occur in both benign and emotional circumstances (Beevers, 2005; Power & Dalgleish, 1997; Teasdale & Barnard, 1993). One of the earliest multilevel theories was the Interactive Cognitive Subsystems (ICS) of Teasdale and Barnard (1993). The ICS theory proposes that there are multiple codes (various forms of information), which are stored at two levels of meaning: generic and specific. These codes can be converted to one another, but are stored in separate memory systems. Emotion-related schematic models contain features of protypical situations that have elicited the emotion in the past. Generic meanings typically activate such schema and are overgeneralized and maintained in a cognitive loop in most forms of psychopathology. This model has been further expanded by Power and Dalgleish (1997, 2008), incorporating substantial information from emotion theory (attempting to account for most forms of psychopathology via the five basic emotions), and cognitive theory (in a highly complex model including four levels of representations of information).

The empirical status of CBT theories is strong and developing further. Recent studies have suggested the potential causal role in attentional and interpretive biases in developing anxiety (see Mathews & MacLeod, 2005). Longitudinal studies are demonstrating the importance of specific forms of cognition on the development of psychopathology (Bryant & Guthrie, 2007; Huppert, Foa, McNally, & Cahill, 2008) and, as described later, a number of studies have demonstrated that changes in cognitive and behavioral mechanisms proposed to be core aspects of CBT theories are related to symptom improvement (Huppert et al., 2008; Ingram, 2007). Overall, current CBT theories of psychopathology have incorporated findings from many areas of experimental psychopathology, basic areas of psychology, and neuroscience, allowing for

further development of current notions of psychological processes in our understanding of the nature and treatment of psychopathology.

## The Process of Therapy

Prior to discussing the specific CBT focus, techniques, and processes it is important to note that the CBT focus on techniques, although essential, is conducted within the context of a therapeutic relationship. In many forms of CBT, the therapeutic relationship is established during the initial evaluation and sessions. Data suggest that the therapeutic alliance in CBT is quite strong and positive, and that therapists are seen as warm, caring, and authoritative (although not authoritarian) (Keijsers, Schaap, & Hoogduin, 2000), which is indeed the goal. In addition, the therapeutic stance is one of genuineness, transparency (the therapist provides a general framework of what will happen in therapy, and discusses the plan for each session at the beginning of the session), and collaborative empiricism (explicitly working together toward a common goal of understanding the patient's problems by testing out hypotheses generated by the patient and therapist). Socratic questioning is used, with the goal of having patients contemplate and process information fully, making them more likely to remember and apply it. Most CBT therapies do not emphasize discussions of the therapeutic relationship as a facilitator of change unless there are reasons to believe that ignoring such issues will interfere with the treatment from the outset (e.g., Linehan, 1993; McCullough, 2003; Young, Klosko, & Weishaar, 2003). In fact, data suggest that the improvements in the therapeutic alliance in CBT may follow cognitive change and symptom reduction rather than precede them, at least in some forms of CBT (e.g., Tang & DeRubeis, 1999). At the same time, since the beginning of CBT, the context of a positive therapeutic relationship has been emphasized (c.f., Chapter 3 in Beck, Rush, Shaw, & Emory, 1979), and other data suggest that patients' perceptions of therapist empathy predicted changes in outcome, whereas changes in outcome did not predict perceptions of therapist empathy (Burns & Nolen-Hoeksema, 1992). Overall, the role of the therapeutic relationship in CBT is seen as important, but not the essential ingredient (see Castonguay, Constantino, McAleavey, & Goldfried, 2010). This is also demonstrated by the efficacy of self-help using CBT for a number of disorders (Newman, Erickson, Przeworski, & Dzus, 2003).

The basic focus in most forms of CBT is on the thoughts, behaviors, physical sensations, and emotions experienced by the patient, which are typically related to their presenting complaint or form of psychopathology. The main concept is to understand the context of problematic situations for the patient by examining recent situations in which the individual experienced an extreme or excessive emotional or behavioral response (fear, shame, embarrassment, depression, anger, etc.). The thoughts, appraisals, and beliefs, behavioral responses (typically in order to cope by avoiding, suppressing, distracting, etc.), and physiological responses are examined in a detailed fashion in order to understand the pattern of responses that the patient engages in, in response to such situations (i.e., a careful functional analysis).

Most forms of CBT encourage a process of emotional engaging in the memory of the situation (to facilitate "hot cognitions" or "emotional processing") followed by some level of distancing. The distancing may be in the form of cognitive challenging (reevaluating the thoughts that occurred in the situation), or examining the alternative behaviors that could have been engaged in (exposure to feared experiences).

All forms of CBT ultimately attempt to actively create new learning experiences (modify associations of meaning within the multiple levels of schemata; Boswell, in press), although different streams of CBT will emphasize different methods of doing so. More behavioral forms of treatment (such as exposure therapy for anxiety disorders or behavioral activation for depression) will emphasize changes in behavior to facilitate new learning, whereas cognitive approaches will emphasize methods of testing predictions and thoughts via cognitive challenging and behavioral experiments. Ultimately, most schools of CBT incorporate behavioral strategies with cognitive strategies, oftentimes within the same exercise. The therapist's goal is to use the power of the relationship and the power of persuasion to help the patient engage in experiences that challenge his beliefs about himself, the world, and the future.

A number of techniques are common to most (although not all) forms of CBT. These include psychoeducation, monitoring, cognitive restructuring, in-vivo exposure, imaginal exposure, behavioral activation, and homework assignments. These techniques are tailored to the individual patient, to target the core problems that appear to be maintaining pathological emotions, thoughts, and behaviors. An individualized case conceptualization is essential, where one takes into consideration both the presenting disorders and the patients' unique contributions to the problems they are experiencing.

Ultimately, the information and techniques utilized in the therapy office are seen as mechanisms to facilitate learning and that need to be generalized to real-world situations. Most cognitive, behavioral, emotional patterns of living cannot be changed via treatment occurring one hour a week. At times, this means doing therapy outside of the office (especially with exposures) to facilitate generalization, but it most commonly includes completing homework assignments, one of *the sine qua non* of CBT. Homework's importance has been researched relatively thoroughly and shown to be a significant predictor of outcome in CBT (Kazantzis, Deane, & Ronan, 2000). Conceptually, the use of homework in CBT is similar to that of learning a new language. As such, one needs to immerse oneself in the language if one is to be fluent enough to use it difficult situations. Although the therapy sessions may provide the basics of grammar and vocabulary for the language, only by using it in every opportunity can one truly master it and be able to use it independently even long after treatment. This metaphor is often provided directly to the patient as homework rationale.

### *Empirical Support*

Over the last 30 years, there have been many advances and developments in both behavioral and cognitive aspects of the treatment, including an abundance of treatment outcome studies demonstrating CBT's efficacy for most forms of psychopathology including anxiety disorders, depression, eating disorders, schizophrenia, personality disorders, and more (for a review of meta-analyses see Butler, Chapman, Forman, & Beck, 2006). In fact, outcome research on CBT comprises the lion's share of the empirical evidence for the effectiveness of psychotherapy via randomized clinical trials. There has also been substantial progress in demonstrating the durability of CBT over long periods of time, from 1 to 10 years for many treatments (Hollon, Stewart, & Strunk, 2006), and that outcomes in practice are similar to those obtained in randomized trials (Stewart & Chambless, 2009). These studies have included careful studies of mechanisms, randomized trials versus medications, placebos, and therapy controls. Results of these trials have had major implications in various health-care environments throughout the world. First, the majority of treatments considered to be empirically supported are CBT-oriented (c.f., Barlow, 2008; Nathan & Gorman, 2007). Second, health-care systems (whether insurance or governmental) have begun to allocate significant funding to the dissemination of CBT treatments, with the notion that such dissemination will ease both burden of illness (e.g., unemployment, time off from work, etc.) as well as decrease service utilization (for two examples, see the National Institute for Clinical Excellence in the UK, www.nice.org.uk and the USA Veterans' Affairs Central Office Initiative (http://www.avapl.org/pub/2009%20Conference/Presentations/AVAPL%202009%20-%20Karlin.pdf). Finally, given the results of clinical trials showing the equivalent effectiveness or superiority of CBT over medications for some conditions, psychiatric guidelines are increasingly calling for CBT to be a first-line treatment for many disorders, including anxiety disorders, eating disorders, and affective disorders (see http://www.psychiatryonline.com/pracGuide/pracGuidehome.aspx).

In addition to the substantial body of research supporting the efficacy and effectiveness of CBT, research has also supported the importance of many of the main tenets of the theories and use of many of the specific techniques. For example, a number of studies have demonstrated the relationship between cognitive change and symptom change (see Huppert et al., 2008 or Ingram, 2007 for reviews, or Tang & DeRubeis, 1999 for a specific example). In addition, numerous studies have shown the relationship between exposure techniques and outcome (see Foa et al., 2006), and between homework and outcome (Kazantzis et al., 2000). More sophisticated data-analytic procedures continue to provide specific tests of CBT theories (see Ingram, 2007). Although data are overall supportive, results are far from definitive, and more research examining CBT theories is clearly warranted.

Cognitive-behavioral therapy is a rich, creative, and effective set of treatments that have been developed over the last 50-plus years. The demand in CBT for assessment, application of idiographically tailored empirically validated techniques (followed by further assessment), and the desire to help achieve maximal benefit for the therapy is reflected both on the local (case-by-case therapeutic stance) and macro (treatment studies) levels. Thus, there is constant work on evaluating what is working within CBT and how it can be improved.

## Humanisitic / Experiential Approach

The most central characteristics of humanistic approaches to psychotherapy are promoting in-therapy *experiencing*, a belief in the uniquely human *capacity for reflective consciousness* plus a *positive view* of human functioning based on the operation of some form of *growth tendency*. Humanistic approaches adopt a

consistently *person-centered* view that involves concern and real respect for each person. Major approaches within this orientation are person-centered, Gestalt, psychodrama, and existential. Some more contemporary experiential therapies, such as emotion-focused (Greenberg, 2002) and experiential therapy (Gendlin 1996; Mahrer 2005), based on a neo-humanistic reformulation of the earlier classic humanistic values, have emerged. In these, the traditional humanistic assumptions have been expanded to incorporate modern views on emotion, dynamic systems, constructivism, and the importance of a process view of functioning to help clarify the humanistic views of growth and self-determination.

### Models of Function and Dysfunction

A general principle that has united all experientially oriented theorists is that people are wiser than their intellects alone. In an experiencing organism, consciousness is seen as being at the peak of a pyramid of nonconscious organismic functioning. Of central importance is that tacit experiencing is seen as potentially available to awareness, as an important guide to conscious experience, and is fundamentally adaptive. In addition, behavior is seen as the goal-directed attempt of people to satisfy their perceived needs, to maintain consistency (Rogers, 1951; Perls, Hefferline, & Goodman, 1951) and, more recently, to regulate affect (Greenberg, 2008).

Internal tacit experiencing is most readily available to awareness, when the person turns his or her attention internally within the context of a supportive interpersonal relationship. Interpersonal safety and support are thus viewed as key elements in enhancing the amount of attention available for self-awareness and exploration. Experiments in directed awareness, in addition, help focus and concentrate attention on unformed experience and intensify its vividness. The classical humanistic–experiential theories of functioning posited two main structural constructs, self-concept and organismic experience, as well as one major motivational construct, a growth tendency. An additional important concept was that of an organismic valuing process.

Rogers developed the most systematic self-theory and equated the self with the self-concept. For Rogers, the self was viewed as an organized *conceptual* system consisting of the individual's perceptions of self, of self in relation, as well as the perceived *values* attached to these perceptions. Needs were seen as important determiners of behavior, but a need was thought to be satisfied only through the selection and use of behavior that was consistent with the self-concept. In contrast to the self-concept, Rogers (1959) defined experience as all that is "going on" within the organism that at any moment is potentially available to awareness. Awareness of in-the-moment embodied "goings-on" was thought essential to being able to access the information implicit in organismic intelligence.

Experiential theorists posit a core human tendency toward growth. Rogers defined an actualizing tendency as the "inherent tendency of the organism to develop all its capacities in ways which serve to maintain or enhance the organism" (Rogers, 1959, p. 196). This view asserted that the person was not solely guided by regulating internal deficiencies, but also was a proactive and self-creative being organized to grow. Neither Rogers nor Perls saw actualization as the unfolding of a genetic blueprint. Rather, they were committed to the concept of an inherent organismic tendency toward increased levels of organization and evolution of ability. Maslow's (1954) concept of hierarchy of needs, from survival to being needs, was also incorporated into the humanistic understanding of motivation.

Rogers explicitly, and Perls implicitly, also proposed an *organismic valuing* process, believing that experience provided an embodied, felt access to this organismic valuing capacity. Organismic valuation is thought to measure how present events are consistent with, respect, and serve important organismic needs. This proposed organismic evaluation does not provide a logical valuation of truth or falseness, but rather a global apprehension of the meaning of events in relation to lived well-being. This valuing process was proposed to be the governor of functioning.

Humanistic theorists see the self as central in explaining human functioning. A central assumption is that to avoid anxiety the person must "maintain" the experience of consistency between an acceptable self-concept and both organismic experience and behavior, and that individuals limit awareness of current feelings and needs that may motivate self-inconsistent behavior. This disowning of feelings and needs is viewed in the long run to lead to maladjustment and to the thwarting of actualization.

Additional concepts recently introduced by neo-humanistic perspectives are affect regulation as a core motive, emotion schemes as central structures, and "voices of self-organizations" as aspects of functioning (Greenberg, 2002; Stiles 1999). Behavior is then seen as being motivated by the desire to have the emotions one wants and not have the emotions one does not want. Emotion schemes are internal organizations of past lived emotional experience

that, when activated, produce current emotional experience. People are seen as multivocal, with many different interacting self-organizations, and the inter-linked traces of experiences into emotion schemes, when activated, form a *community of voices* within the person. Unintegrated voices tend to be problems, whereas assimilated voices are resources, available when circumstances call for their unique features and capacities.

## HEALTHY FUNCTIONING

All humanistic/experiential theorists view the person as a complex self-organizing system. The greater the awareness of experience of the self, and the field or environment in which the person is operating, the greater the integration of all aspects of experience and the more engagement with the environment. In this view, it is the integration in awareness of all facets and levels of experience (Greenberg & Safran, 1986; Mahrer, 2005; Perls, 1969; Resnick, 1995; Rogers, 1961; Schneider & May, 1995; Yalom, 1980) that is seen as important in healthy function-ing. When functioning well, people can access well-differentiated aspects of self as an immediate felt referent, and use it as an online source of informa-tion to inform present and subsequent behavior (Gendlin, 1962; Rogers, 1957, 1959).

These traditional humanistic assumptions have been expanded by neo-humanistic perspectives to help clarify the humanistic views of growth and self-determination (Greenberg, Rice, & Elliott 1993; Greenberg Watson, & Leitaer 1998). Contemporary *emotion theory* (Frijda 1986; Greenberg & Paivio, 1997; Greenberg & Safran, 1986) holds that emo-tion is a biologically adaptive system that provides rapid appraisals of the significance of situations to peoples' well-being and, therefore, guides adaptive action. Emotion thus provides a process by which the growth tendency and the organismic valuing process function (Greenberg, 2002). In this view, emotion helps the organism to process complex situational information rapidly and automatically, in order to produce action appropriate to meeting important organismic needs (e.g., self-protection, support).

In addition, humanistic perspectives on subjec-tivity and perception have been connected to *constructivist* epistemology and views of functioning. Within this framework, people are seen as dynamic systems in which various elements continuously interact to produce experience and action (Greenberg & Pascual-Leone, 1995, 2001; Greenberg & van Balen, 1998). These multiple interacting self-organizations

can be described metaphorically as "voices" or parts of self (Elliott & Greenberg, 1997; Mearns & Thorne, 1988; Stiles, 1999). In this view, the "I" is an agentic self-aspect or self-narrating voice that constructs a coherent story of the self by integrating different aspects of experience in a given situation; however, this voice has no special status as an "executive self."

In a neo-humanistic view, growth is seen as emerging, not only through the self-organization of some type of biological tendency, but also from gen-uine dialogue with another person. In such an I–Thou dialogue (Buber, 1978), each person is made present to and by the other. In therapy, the therapist both *contacts* and *confirms* the client by focusing on particular aspects of the client's experiencing. Contact involves a continual empathic focus by the therapist on the client's subjective experience, confirming the person as an authentic source of experience and strengthening the self. Confirmation validates the other and, by focusing on strengths and internal resources, promotes growth. It is the therapist's focus on subjective experience and strengths that helps facilitate client growth and development.

## DYSFUNCTION

In general, experiential approaches viewed pathology as resulting from the inability to integrate certain experiences into existing self-organization. From the experiential perspective, what is unacceptable to the self is dealt with, not by expelling it from con-sciousness but by failing to own experience as belonging to one's self (i.e., not experiencing it). In addition, what is disowned is not by definition pathogenic. Therefore, in the experiential perspec-tive, because healthy experiences and feelings may be seen as unacceptable by other self-organizations, they are as likely to be disowned as are unhealthy feelings or trauma. Experiential theory therefore sees dysfunction as occurring both from the disown-ing of healthy growth-oriented resources and needs, as well as from the avoidance of painful emotions.

In the neo-humanistic process view, it is the *inability to integrate* aspects of functioning into coherent harmonious internal relations that is viewed as a major source of dysfunction, rather than incongruence between self-concept and experience. Thus, different voices in the self representing one's wishes and fears, one's strengths and vulnerabilities, or one's autonomy and dependence may at any moment be in conflict and at any moment in danger of being disowned. Notice that conflict here is between different self-organizations, not conscious versus unconscious, or moral versus immoral.

The second central source of dysfunction is the *inability to symbolize bodily felt experience* in awareness. Thus, one may not be aware or be able to make sense of the increasing tension in one's body, of the anxiety one feels, or of unexpressed resentment, and this will lead to being out of touch with how one feels and, therefore, disoriented and unable to act most adaptively. A third major source of dysfunction involves the activation of *core maladaptive emotion schemes*, often trauma-based (Greenberg & Paivio, 1997). This leads to painful emotions and emotional memories and to maladaptive emotional experience and expression or the avoidance of these. The operation of this process implies that not all basic internal experience is an adaptive guide, and that, in addition to the benefits of becoming aware of basic experience, basic experience itself sometimes requires therapeutic change.

The above three general processes of dysfunction are supplemented by the operation of a large variety of more specific cognitive/affective processing difficulties that help explain different types of dysfunctional experiential states. A variety of particular experiential difficulties have been described by Greenberg, Ford, Alden, and Johnson (1993). Difficulties such as problematic reactions, in which one's view of an experience and one's reaction don't fit; self-evaluative splits, in which one part of the self negatively evaluates another; unfinished business, involving unresolved emotional memories; and statements of vulnerability involving a fragile sense of self. All involve different types of underlying emotion-schematic processing problems. Each state requires different interventions designed to deal with the specific emotional processing problems. This focus on different problematic in-session states offers a differential view of dysfunction in which current determinants and maintainers of disorders are identified by a form of process diagnosis in which therapists identify markers of in-session opportunities for implementing specific types of interventions and change processes.

## The Process of Therapy

In the most general terms, humanistic–experiential therapy is based on two basic principles: first, the importance of the relationship; and, second, the consistent and gentle promotion of the deepening of the client's experience.

### THE RELATIONSHIP

The relationship is seen as both curative, in and of itself, and as facilitating of the main task of therapy; that is, the deepening of client experiencing.

The relationship is built on a genuinely prizing empathic stance and on the therapist guiding clients' experiential processing toward their internal experience. An active collaboration is created between client and therapist, in which neither feels led, or simply followed by the other. Instead, the ideal is an easy sense of co-exploration. Although the relationship is collaborative, when disjunction or disagreement does occur, the therapist defers to the client as the expert on his or her own experience. Thus, therapist interventions are offered in a nonimposing, tentative manner, as conjectures, perspectives, "experiments," or offers, rather than as expert pronouncements or statements of truth. Interventions are construed as offering tasks on which clients who are active agents can work, if they so choose. Maintaining a responsive relational bond always takes precedence over the pursuit of a task. Although the therapist may be an expert on the possible therapeutic steps that might facilitate task resolution, it is made clear that the therapist is a facilitator of client discovery, not a provider of "truth," nor a psycho-educator. Experiential therapy thus recognizes both the power of the understanding relationship and the importance of different in-therapy tasks in promoting different types of therapeutic change.

### STRATEGIES AND INTERVENTIONS

In experiential therapy, deepening experiential processing and subsequent meaning construction is accomplished by (a) creating a safe, trusting environment conducive to experiential processing and providing emotion coaching that models approach, valuing, and acceptance of emotion; (b) providing words for understanding and symbolizing a person's unformulated experience to help the client both regulate and express experience; (c) directing the client's attentional resources to the edges of awareness; (d) using empathic exploration and evocation to activate tacit meanings, bring them emotionally alive, and explore what is at the periphery of awareness; and, finally, (e) using emotion-stimulating interventions to activate emotional experience to help the client access and express alternative adaptive emotional resources (Greenberg, 2002).

The purpose of deepening emotional processing in experiential therapy is to activate internal emotional resources in the client; that is, the client's adaptive tendencies and resources toward adaptive growth (Gendlin, 1962; Greenberg 2002; Rogers, 1957). As clients access an experience of their feelings, they will also experience related needs, as well as action tendencies that may actualize the meeting

of these needs in the world. Although accessing internal emotional resources is thought by some to occur sufficiently in a person-centered relationship, experiential therapists work toward accessing alternate emotional resources of the client in more focused ways by the use of specific techniques. These may include experiments in attention, focusing, working directly with embodied expression, and by empty-chair and two-chair dialogues (Greenberg et al., 1993; Greenberg & Watson, 2006).

EXPERIENTIAL THERAPY AS PROCESS THEORY
An important distinguishing characteristic of experiential therapy is that it offers a process theory of how to facilitate experiential knowledge, and rather than a content theory of personality or psychopathology, it offers a process theory that specifies both the moment-by-moment steps in the client's process of change and the therapist interventions that will facilitate these steps. The emphasis in each step always is on how to promote the direct sensing of what is concretely felt in the moment to create new meaning and how to promote a next processing step.

The key to experiential therapy is to have clients experience content in a new way, so that this new experience will produce a change in the way they view themselves, others, and the world. Experiential therapy thus emphasizes that symbols, schemes, and even behavior must interact with the body-based, experiential, level of existence in order to produce change (Gendlin, 1996). It thus offers a process theory of how body and symbol interact, and a set of methods for promoting this process.

Case formulation in this approach involves an unfolding, co-constructive process of establishing a focus on the key components of the presenting problems (Greenberg & Goldman, 2007). Formulation emphasizes making process diagnoses of current in-session states and exploring these until a clear focus on underlying determinants emerge through the exploratory process. In developing a case formulation, the therapist focuses first on salient poignant feelings and meanings, follows the client's emotional pain, and notices the client's initial manner of cognitive-affective processing and what will be needed to help the client focus internally. Then, working together, client and therapist develop a shared understanding of the underlying emotional determinants of the presenting problem, the main therapeutic tasks and, finally, of the client's emerging foci and themes. Case formulation emerges from this dialogue and is a shared construction involving deeper understandings of the problem and goals of treatment. The defining feature of an experiential approach to case formulation and assessment is that it is *process-diagnostic and marker-focused* (Greenberg et al., 1993) rather than person-diagnostic. Diagnostic focus is on in-session problematic processes in which clients are currently engaged.

Differential process-diagnosis involves the therapist attending to a variety of different *in-session markers* of in-the-moment problematic states. Problematic states are then addressed by interventions designed to address the specific difficulty. These processes may include process markers of clients' emotional processing style, such as being externally focused or emotionally dysregulated, or of particular problem states, such as self-critical conflict or unresolved bad feelings toward a significant other. Attention is paid to *how* clients are presenting their experiences in addition to *what* they are saying. Formulation and intervention are therefore constantly and intimately connected, span the entire course of treatment, and occur constantly at many levels.

*Empirical Support*
A series of meta–analyses of controlled and uncontrolled studies on the outcome of humanistic-experiential therapies have demonstrated their effectiveness (Greenberg, Elliott, & Lietaer, 1994). Elliott, Greenberg, and Lietaer (2005) presented a meta-analysis of 64 studies of experiential therapies. Eighteen examined emotion-focused individual therapy (EFT); ten evaluated EFT for couples; ten studied Gestalt therapy, 11 investigated encounter/sensitivity groups, and 15 looked at the outcome of various other experiential–humanistic therapies (e.g., focusing-oriented, psychodrama, or integrative). The average pre–post effect size was .99, considered large. Clients maintained or perhaps even increased their post-treatment gains over the post-therapy period, with largest effects obtained at early follow-up. Control-referenced effect sizes of pre–post differences in the 42 treated groups in which experiential treatments were compared to waitlist or no-treatment controls were also considered large.

Results of 74 comparisons between experiential and nonexperiential therapies showed no overall difference between experiential and nonexperiential treatments. In 60% of the comparisons, no significant differences were found. In 18% of comparisons, clients in nonexperiential treatments did significantly better; whereas in 22% of comparisons, experientially treated clients did significantly better. A subsample of 46 studies compared effects between experiential and CBT. In general, experiential therapies

and CBT therapies were shown to be equally effective.

As an example of a humanistic approach that has been empirically studied, process experiential emotion-focused (PE/EFT) therapy, was found to be highly effective in treating depression in three separate trials. In two studies PE/EFT was compared to a purely relational empathic treatment, and one study compared PE/EFT to a cognitive behavioral treatment. All three treatments were found highly effective in reducing depression. Process experiential emotion-focused therapy was found to be more effective than a pure relational empathic treatment in reducing interpersonal problems, in symptom reduction, and in preventing relapse (Goldman, Greenberg, & Pos, 2005; Greenberg & Watson, 1998). Watson, Gordon, Stermac, Kalogerakos, and Steckley (2003) found no significant differences in symptom improvement between PE/EFT and CBT for the treatment of major depression. However, clients in PE/EFT therapy reported being significantly more self-assertive and less overly accommodating at the end of treatment than did clients in the CBT treatment. In addition, EFT has been shown to be effective in treating childhood trauma, abuse, and interpersonal injuries (Paivio & Greenberg 1995; Paivio, Hall, Holowaty, Jellis, & Tran, 2001).

The majority of research on experiential psychotherapy has focused on whether depth of experiencing relates to outcome. Hendriks (2002) has reviewed 91 of these studies. Experiential processing was explored within various treatments (not solely experiential) for varied diagnostic categories, from schizophrenia, to marital discord, to depression. The vast majority of studies found that the higher experiencing levels measured related to better psychotherapy outcomes, as measured by a variety of outcome measures.

## Systemic Approach

The essence of the systemic approaches to psychotherapy is their focus on contextually defining and conceptualizing clients' psychological problems. Most often, the context or frame of interest is the couple or the family, but it may also be a broader context, such as an extended family or classroom of students and teacher. Although assessment and case conceptualizations are informed by this perspective, in practice, specific interventions are directed not only at the family or couple but may also be directed at an individual. As discussed later, there are numerous approaches to systemic therapy. What specifically, then, defines a systemic approach to therapy,

and how do systemic approaches differ from other approaches? To fully answer these questions, we consider both the defining features of systemic therapy models and their evolution as a distinct approach to treatment. This is followed by a detailed description of selected systemic therapy approaches, followed by a summary of outcome and change process research.

### Models of Function and Dysfunction

Although systemic therapies can differ from each other substantially in practice, they share certain common philosophical and conceptual features that distinguish them from other therapy approaches. Most importantly, systemic therapies focus not solely on *intra*personal or individual dynamics, but rather on the *inter*personal and *inter*actional dynamics that shape and maintain problems in one or more members of the system. A system (e.g., couple, family) is a set of dynamic elements (e.g., people) that mutually act upon, and are acted upon, by the others. For example, in a couple, the emotional or physical avoidance of one partner may "cause" the other to approach the partner, which in turn begets more avoidance behavior by the partner, then more approach behavior by the first person, and so on. Although the partners themselves often punctuate this ongoing sequence in a linear way that blames the other and exonerates themselves ("she started it," "I wouldn't bug him if he didn't avoid me"), the systemic therapist takes a "metaperspective," focusing instead on circular causal explanations of the ways in which the couples' joint pattern of interacting sustains their unhappiness.

The same is true in the family context. Systemic therapists assess a child's problem behavior by considering it, not in isolation, but within the context of the family system. For instance, a child's externalizing behaviors may function to draw a distant parent into more contact with the other parent and the child, or to deflect conflict between the parents onto the child. Each person's behavior is part of a web of elements in which the whole is more than the sum of its parts. Thus, explanations of psychopathology in an individual require an expansion of the frame of reference: "If a person exhibiting disturbed behavior (psychopathology) is studied in isolation, then the inquiry must be concerned with the *nature* of the condition and, in a wider sense, with the *nature* of the human mind. If the limits of the inquiry are extended to include the effect of this behavior on others, their reactions to it, and the context in which all of this takes place, the focus

shifts from the artificially isolated monad to the *relationship* between parts of the system. The observer of human behavior then turns from an inferential study of the mind to the study of the observable manifestations of relationship" (Watzlawick, Beavin, & Jackson, 1967, p. 21).

Early theorizing and clinical observation yielded a number of heuristically rich corollaries that provide the underpinnings for systemic models. The first assumption is that communication is the vehicle by which relationships (both healthy and disturbed) are defined, and thus much is learned from a study of not just *what* people within a system say to each other, but *how* they say it. Tone of voice, sarcasm, humor, interruptions, kinesics, even silence, communicate information about not only the content of the communication and how to "read" it, but also about the relationship itself. Another assumption is that family and other human systems have a kind of psychological equilibrium that is maintained by positive and negative feedback to the system. Negative feedback is information that signals a deviation from the steady state (homeostasis) and the necessity of some self-regulating adjustments (e.g., when an adolescent's emerging needs for independence feeds conflict and results in shifts in established family patterns of interaction). Positive feedback is information that signals, "we are on course, no change is needed." Since, in a family system, the behavior of each person continually provides feedback to the others, the result is a complex and dynamic system in which "concepts of pattern and information" (Watzlawick et al., 1967, p. 32) are the focus of clinical assessment. This stands in contrast to most other psychotherapy approaches, in which characteristics of individuals—intrapsychic drives and conflicts, problematic affective states, or distorted cognitions—are the focus.

At the time it was developed, in the late 1960s, the systemic model was a radical shift from the psychoanalytic, psychodynamic, and humanistic psychotherapy approaches that were dominant; it developed in parallel, however, with the emerging behavioral therapies that were applied to families. Some of these assumptions have subsequently been challenged or refined in newer systemic therapy approaches. However, they served to further define the transformative nature of the systemic approach. Although systemic approaches are now firmly established, they continue to present interesting challenges to traditional assumptions and habits of thinking on questions such as: Who is the client? How should change be measured? How can we classify and assess distressed relationships and family systems? (See Kaslow, 1996; Kaslow & Patterson, 2006, for discussion of relational diagnosis.)

Current systemic therapies must be understood within the context of their evolution (see Becvar, 2003, for an excellent summary). From the beginning, systemic therapy has had broad interdisciplinary roots. It was born of the exchange of ideas and in some cases, actual collaborations between those interested in general systems theory in the biological sciences, mathematicians, communications researchers, anthropologists, and psychiatrists (Ruesch & Bateson, 1968; von Bertalanffy, 1950; Watzlawick et al., 1967; Watzlawick, Weakland, & Fisch, 1974; Weiner, 1948). Translation and use of these ideas in clinical settings and early forms of family therapy in the 1960s and 1970s were powerful, generative, and occasionally misguided, as in the case of the double-bind theory of schizophrenia (Bateson, Jackson, Haley & Weakland, 1956). The fact that this *was* a radically different view of psychological problems no doubt accounted for the development, in some of its applications, of a singular, if not zealous, focus on the system to the exclusion of the individual, leading some to question whether the "self" had been lost in the system (Nichols, 1987). As major advances were made in the 1980s and 1990s, in understanding the role of cognition and emotion in psychopathology, the role of attachment in adult relational problems, and the ways in which brain biochemistry both affects and is affected by experience, these developments became incorporated into the newer evolving forms of systemic family and couples therapies. As will become clear shortly, these newer approaches integrate both individual-level and systems-level dynamics in their theories and practice.

### The Process of Therapy

Current systemic therapy interventions draw heavily on the foundations established by the "classic" approaches, e.g., behavioral family therapy (Falloon, 1991; Patterson, 1971), structural family therapy (Colapinto, 1991; Minuchin, 1974), strategic therapy (Haley, 1963, 1973; Madanes, 1981), and interactional/MRI approaches (Segal, 1991; Watzlawick et al., 1974). They are, however, more integrative and more cognizant of the ways in which systems outside the nuclear family and the forces of gender, race, culture, and socioeconomics interact with the family system. And there are a few models that marry systemic thinking with postmodern philosophy, the "social construction therapies"

(Anderson, 2003). Two systemic approaches are described in some detail here. They were chosen from the many current approaches (see Gurman & Jacobson, 2002, and Lebow, 2005) as illustrations of the variety of interventions that characterize systems treatments, and because they each have strong empirical support.

### Brief Strategic Family Therapy

Brief strategic family therapy (BSFT; Santisteban, Szapocznik, Perez-Vidal, Kurtines, Murray, & LaPerriere, 1996); Szapocznik & Kurtines, 1989; Szapocznik, Perez-Vidal, Hervis, Brickman, & Kurtines, 1990) is a set of interventions for families of adolescents with externalizing behavior problems, such as conduct disorder and delinquency, as well as substance abuse. Brief strategic family therapy focuses on the dysfunctional family relationship patterns that are associated with these (often, co-occurring) problems. It also targets the school and peer systems. Brief strategic family therapy entails three steps, each equally important (Horigian et al., 2005). *Joining* is the first step, and BSFT has pioneered techniques that work for engaging difficult families, including (a) consultation by phone, even before therapy starts to get family members to come in; (b) forming an early alliance with each family member to learn what his or her goals are to enable work toward them; and (c) successfully joining the family system by working within existing structures at first. The therapist's goal is to become a trusted, temporary leader of the family, one who is seen by each member as both respectful and capable of helping them resolve their problems. The therapy was developed with Hispanic families and is especially attuned to cultural considerations, including respect for the most powerful family members.

In the next step, *diagnostic assessment,* the therapist creates enactments in the sessions that allow him or her to assess the family's typical patterns of interactions by observing them *in vivo* rather than just hearing accounts of them. The BSFT therapist studies their organization (leadership, subsystems, communication), resonance (emotional connections between them), and their developmental stage as a family. He or she also notes which member is the "identified patient" and the family's conflict resolution style. This assessment allows the therapist to develop a formulation of how the family interactions are sustaining the problem behaviors and from that, to launch the third step, *restructuring* their maladaptive styles of interaction to healthier ones. Working with the family conjointly, the BSFT

engages the family in active work on the here-and-now process of how they interact with each other during the sessions. Brief strategic family therapy training and the therapy manual (Szapocznik, Hervis, & Schwartz, 1993) provide directions for orchestrating change via techniques of reframing, assignments that create shifts in boundaries and alliances, and tasks within the therapy session and (once they have been successfully completed there) outside of it; for example, parents talk together to establish a curfew. Treatment typically lasts 12–16 sessions, with booster sessions as needed, and it ends when both family functioning and the adolescent problem behavior are significantly improved. There is also a one-person form of BSFT for those families that cannot be engaged as a whole (Szapocznik, Kurtines, Foote, & Perez-Vidal, 1986).

### Emotionally Focused Couple Therapy

Emotionally focused couple therapy (EFT; Greenberg & Goldman, 2008; Greenberg & Johnson, 1988; Johnson, 1996; Johnson & Greenberg, 1994; 1985; Johnson et al., 2005) is also a brief, structured treatment that focuses on emotion and relational bonds together, in order to decrease couple distress and dissatisfaction. Specifically, EFT interventions are targeted at "identifying the negative cycles of interaction, accessing the emotions that are both a response to and organizers of these cycles, and reprocessing these emotions to create new responses that shape secure bonding events and new cycles of trust and security" (Woolley & Johnson, 2005, p. 387). The therapy proceeds through three stages: *deescalation of negative cycles, restructuring interactional positions toward secure connection,* and *consolidation and integration.* Although these are articulated sequentially, the work proceeds in an iterative fashion, and setbacks may require some backtracking, so that in actual practice, the couple and therapist may be working on more than one step at once. *Deescalation* is accomplished by active involvement of the therapist, beginning with building an alliance with each partner individually (there may be long stretches where the therapist is talking with one person empathically while the other just listens) to establish safety and security within the therapeutic relationship. As in BSFT, the therapist then observes the clients' relational behavior to identify the negative interaction cycle; with couples, this is often a pattern such as pursue/withdraw, blame/placate, criticize/defend. The therapist then uses gentle but persistent experience-focused questions to access and bring out the previously unacknowledged

attachment emotions that underlie the patterned interactions (e.g., feelings of being unworthy, fear of abandonment). The other partner, of course, is a witness to this work but is enjoined from jumping in to defend him or herself, to invalidate the others' emotional experience, etc. This stage culminates in the therapist articulating a construction of the problem in terms of how each partner's underlying emotions and attachment needs are related to their negative and jointly created interactional cycle. This is done matter-of-factly, avoiding blame, and striving to keep each partner feeling understood and supported by the therapist as the second stage is entered.

Here, the work deepens, as the therapist focuses in on the disowned emotional needs and works toward the central change events, "withdrawer reengagement" and "blamer softening." Theoretically, the outcome of this work—although it may take a while—is the partner's acceptance of the other's emotional experiences and resulting shifts in interactional positions that allow partners to share their needs and wants directly, becoming closer and more emotionally engaged as a couple. This undermines the rigid, conflictual patterns of relating. In the final stage, the work is about consolidating the new ways of relating and integrating them reliably into their life together beyond the therapy sessions.

### Empirical Support

There is strong empirical support for the efficacy of couple and family systems therapies as a class of therapy (Pinsof & Wynne, 1995; Sexton, Alexander & Mease, 2004). But because these therapies are myriad and diverse, the better question is, *which* approaches have empirical support? In general, solid empirical support is strongest, but not limited to, those therapies with a strong behavioral or cognitive behavioral focus.

In the couples' therapy domain, behavioral couple therapy (BCT: Jacobson & Margolin, 1979) and integrative behavioral couple therapy (IBCT), which adds an acceptance component to traditional behavioral couple therapy (Baucom, Christensen & Yi, 2005; Christensen & Jacobson, 1998), insight-oriented marital therapy (IOCT; Snyder, 1999; Synder & Wills, 1989), and EFT have been demonstrated in clinical trials to be more effective than no treatment and about equally effective as each other (Sexton et al., 2004). However, a robust finding in this literature is that couples' therapy of *any* kind results in significant improvements in relationship satisfaction for under 50% of couples and that, even

for those couples, gains in relationship satisfaction erode significantly within a year after treatment (Snyder, Castellani, & Whisman, 2006).

In the family therapy domain, again, certain approaches have strong empirical support. These include: functional family therapy (FFT; Sexton & Alexander, 2003), multisystemic family therapy (MST; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998), multidimensional family therapy (MDFT; Liddle, 1995), and BSFT (Szapocznik & Kurtines, 1989). Attachment-based family therapy for depressed adolescents (ABFT) has good preliminary empirical support as an effective, distinct model (Diamond, Diamond, & Hogue, 2007; Diamond, Siqueland, & Diamond, 2003). With the exception of the latter, these all share a focus on families with delinquent or substance-abusing adolescents. Other empirically supported family treatments include parent management training for child conduct disorders (Brestan & Eyberg, 1998); psychoeducational family interventions for schizophrenia (Lam, 1991) and bipolar disorder (Miklowitz, George, Richards, Simoneau, & Suddath, 2003; Rea et al., 2003); and systemic treatments for substance-abuse problems (O'Farrell, 1993; Stanton & Shadish, 1997) and adults dually diagnosed with substance-abusing and other Axis I disorders (Moore, 2005).

However, other popular family therapy approaches have simply not yet been adequately tested, and family therapy efficacy research focuses primarily on externalizing disorders of youth. Meanwhile, other approaches, such as strategic therapy (Fisch, Weakland, & Segal, 1982; Madanes, 1981), solution-focused therapy (de Shazer, 1985, 1991), and postmodern social construction therapies, including narrative therapy (White & Epston, 1990) and collaborative therapy (Anderson & Goolishian, 1988), continue to be practiced and developed. Progress in outcome research continues (Sprenkle, 2002), as do ongoing debates about the best ways to assess outcomes and study the process of therapy in a manner compatible with a systemic perspective (Sprenkle, 2002; Sprenkle & Piercy, 2005).

Research on the change process of change is just beginning (Friedlander & Tuason, 2000; Heatherington, Friedlander, & Greenberg, 2005) and is greatly needed. Although the treatments reviewed here are diverse, they share common features and (theoretically) some common change mechanisms that are specific to a systemic approach. These mechanisms should include processes between therapist and clients and also *between the clients*

within the couple or family, as well as *within* individual members of the system. Articulating these mechanisms or "principles of effective change" (Castonguay & Beutler, 2006) and testing them empirically is key to the healthy growth and future of systemic therapies. Christensen, Doss, and Atkins (2005) provide a good illustration of how to articulate transtheoretical, testable principles of change in the couples therapy domain. An example is an "evocative intervention," that, theoretically, facilitates corrective experiences for the couple. In EFT and IBCT (Cordova, Jacobson, & Christensen, 1998), for example, the therapist elicits emotional, less-defensive, more honest, and vulnerable reactions in a partner which, ideally, are processed by the other partner; a "softening" on one person's part feeds "accessibility" on the other's part and, as each person experiences a different sense of self, and a different sense of the other, they draw closer. Evidence supports this theorized change process (Bradley & Furrow, 2004; Greenberg et al., 1993). Another transtheoretical process that has received empirical support is transforming or reframing the clients' construction of the presenting problem. This includes the kind of reframing done in BSFT, the transformation of an individual narrative about the problem to an interpersonal, systemic one in constructivist family therapy (Coulehan, Friedlander, & Heatherington, 1998; Sluzki, 1992), and "relational reframing" of an adolescent's depression as a schism or rupture of trust in the adolescent–parent subsystem in ABFT (Diamond et al., 2003). The evocative intervention and the reframing interventions are good examples of the ways in which contemporary systemic approaches explicitly incorporate individual processes (emotion and cognition, respectively) into theory and therapy practice, in tandem with attention to interpersonal processes. They also illustrate the ways in which systemic thinking continues to be cross-disciplinary, and the ways in which many current approaches have built clinically grounded, testable propositions into the theory itself.

## Psychotherapy Integration

Although a substantial number of psychotherapists identify themselves as eclectic or integrative (Norcross & Goldfried, 2005; Orlinsky & Rønnestad, 2005), the acceptance of psychotherapy integration was a process that evolved over several decades. A seed for psychotherapy integration was first planted by Alexander French, in his address of the 1932 meeting of the American Psychiatric Association (later published as French, 1933). In this address, French drew parallels between psychoanalysis and Pavlovian conditioning (e.g., the similarities between repression and extinction). Subsequently, the potential for psychotherapy integration received attention from only a handful of authors between 1932 and 1960 (e.g., Dollard & Miller, 1950; Rosenzweig, 1936), and did not emerge as a latent theme until the 1960s and 1970s, beginning with Frank's (1961) *Persuasion and Healing*. This book addressed itself to the commonalities cutting across varying attempts at personal influence and healing in general. Soon after, the important concept of "technical eclecticism" was introduced in 1967, by Lazarus, who argued that clinicians could use techniques from various therapeutic systems without necessarily accepting the theoretical underpinnings associated with these approaches. By this time, many clinicians were arguing that, rather than being irreconcilable, techniques from divergent approaches could be viewed as complementary. For example, Wachtel (1975) maintained that many instances of relapse following behavior therapy might possibly be linked to the client's maladaptive patterns that might more readily be identified when reviewed from within a psychodynamic framework.

In 1976, Garfield and Kurtz published findings indicating that approximately 55% of clinical psychologists in the United States considered themselves eclectic (also see Garfield & Kurtz, 1977). Prochaska (1979), in a textbook describing diverse systems of psychotherapy, concluded with a chapter that made the case for developing a transtheoretical orientation that would encompass what had been found to be effective across different approaches to psychotherapy. With these developments, psychotherapy integration became a bona fide movement in the 1980s. An important contribution was made in a seminal paper by Goldfried (1980), who, noting past attempts to find commonalities across psychotherapies, argued that a fruitful level of abstraction at which such a comparative analysis might take place would be somewhere between the specific techniques and theoretical explanations for their potential effectiveness. Goldfried (1980) maintained that it is at this intermediate level of abstraction—the level of clinical strategy—that potential points of overlap may exist.

Another significant event in the history of psychotherapy integration was the formation of an international organization devoted specifically to this endeavor. Formed in 1983, the Society for the

Exploration of Psychotherapy Integration (SEPI) was established as a way of bringing together the growing number of professionals interested in this area. In the mid to late 1980s, in order to provide forums for these many voices, new journals appeared that directly addressed clinical and research issues pertinent to integration. One journal was the *International Journal of Eclectic Psychotherapy*, later renamed the *Journal of Integrative and Eclectic Psychotherapy* in 1987. The 1990s witnessed a continued growth of writing on psychotherapy integration, as well as a continued trend toward more therapists identifying themselves as eclectic/integrative. In 1991, SEPI began publishing its own journal, *Journal of Psychotherapy Integration.* The first edition of the *Handbook of Psychotherapy Integration* (edited by Norcross and Goldfried) was published in 1992, followed by the *Comprehensive Handbook of Psychotherapy Integration* (Stricker & Gold, 1993). These handbooks and journals, as well as the establishment of SEPI, are clear signs that psychotherapy integration has grown from being an idea (or dream) evoked by a few visionaries (and/or heretics within their own schools of thought) to becoming nothing less than a *leitmotif* in psychotherapy textbooks and training programs. For a more comprehensive review of the history of psychotherapy integration, see Goldfried (2005).

### Factors Contributing to Psychotherapy Integration

Although the majority of therapists (at least in the United States) identify themselves as integrative or eclectic (Norcross, 2005), psychotherapy integration has only developed into a defined area of interest in the past 20 years. Of the many factors that have fostered this movement, a number of empirical findings have led numerous scholars and therapists to consider the contributions of a plurality of theoretical orientations in their attempt to both understand and improve psychotherapy (see Castonguay, Reid, Halperin, & Goldfried, 2003).

• Although psychotherapy works, some clients fail to fully improve, others terminate prematurely, and yet others deteriorate.
• Although some treatments (e.g., CBT) appear to be more effective than others for particular clinical problems (e.g., obsessive-compulsive disorder), major forms of psychotherapy tend to have equivalent outcomes.
• Descriptions and observations of psychotherapists (including leading figures such as Freud, Rogers, and Wolpe) suggest that there are differences between their theoretical writings and clinical practice (see Castonguay, 1997; Castonguay et al., 2010; Castonguay & Goldfried, 1994).
• Process research suggests that, in their regular clinical practice, therapists of different orientations can show more similarities than differences (e.g., Goldfried, Raue, & Castonguay, 1998).
• Process research not only demonstrates that factors that are common to different approaches (e.g., the alliance) predict client improvement, but that some variables typically associated with one orientation (e.g., emotional deepening, exploration of attachment to early significant figures) are associated with positive outcome in other orientations (e.g., CBT) (Castonguay et al., 1996; Hayes, Goldfried, & Castonguay, 1996).

In addition to these empirical findings, leaders of major orientations have voiced serious criticisms of their preferred theoretical approaches, while encouraging an open-minded attitude toward other orientations. Strupp (1976), for instance, denounced the "closed-shop" mentality that prevailed in the psychoanalytic milieux and urged his colleagues to consider the contributions of learning theories and research in their conceptualization of therapy. Similarly, Thorensen and Coates (1978) lamented that a complacent orthodoxy was bred within behavioral therapies and that a critical revision of its conceptual rationale (including the consideration of the "purpose of life") was needed.

Furthermore, clinicians of different orientations recognized that their approaches did not provide them with the clinical repertoire sufficient to address the diversity of clients and their presenting problems. For example, Goldfried and Castonguay (1993) argued that CBT has paid limited attention to the therapeutic relationship and emotion. Integrating contributions from psychodynamic, interpersonal, and humanistic approaches, they argued that the examination of the way in which clients interact during sessions, as well as the use of emotional deepening techniques, could help CBT therapists to identify and modify core schemas and maladaptive patterns of interpersonal behavior.

### Pathways of Psychotherapy Integration

There are a number of routes to psychotherapy integration, and these multiple pathways are typically understood to fall into one of four categories: technical eclecticism, theoretical integration, common

factors, and assimilative integration. Research by Norcross, Karpiak, and Lister (2005) reveals that each of these is embraced by a significant number of self-identified eclectics and integrationists.

### TECHNICAL ECLECTICISM

The least theoretical of these pathways, technical eclecticism, seeks to select the best intervention for the person and the problem, based on the best available data. Thus, the foundation is more empirical than theoretical. Examples of technical eclecticism include Lazarus's (2005) multimodal therapy and Beutler's (see Beutler, Consoli, & Lane, 2005) systematic treatment selection and prescriptive psychotherapy (STS). Technical eclectics utilize interventions from different sources without necessarily identifying with the theories that generated them. Unlike theoretical integrationists, there is less interest in the convergence between disparate systems and their connection with specific techniques.

### THEORETICAL INTEGRATION

The most theoretical of these pathways, theoretical integration, seeks to integrate two or more therapies with the intention of developing an overlapping theoretical system that improves upon the constituent therapies alone. An emphasis is placed on integrating the underlying models, along with their theory-specific techniques into an overarching framework. Examples of this approach include Wachtel, Kruk, and McKinney's (2005) effort to integrate psychoanalytic and behavioral theories with cyclical dynamics, and Ryle's (2005) cognitive-analytic therapy. As noted by Norcross (2005) "the primary distinction between technical eclecticism and theoretical integration is that of empirical pragmatism and theoretical flexibility" (p. 9).

### COMMON FACTORS

Stemming from the work of Frank (1961) and Garfield (1980), a common factors approach seeks to elucidate the core ingredients that different therapies share in common. This method is predicated on accumulating research that commonalities across treatments (e.g., the working alliance) may be at least as important in accounting for psychotherapy outcome as the unique factors that differentiate among them. However, it is widely recognized that the debate between common and unique factors in psychotherapy represents a false dichotomy, and these factors must be integrated to maximize effectiveness.

### ASSIMILATIVE INTEGRATION

Assimilative integration was defined by Messer (2001) as "the incorporation of attitudes, perspectives, or techniques from an auxiliary therapy into a therapist's primary, grounding approach" (p. 1). This form of integration calls for a firm grounding in one system of psychotherapy, with a willingness to incorporate practices and views from other systems. This entails adherence to a single, coherent theoretical system that assimilates techniques and interventions from multiple systems into this system. Examples of this approach to integration include Castonguay, Newman, Borkovec, Grosse Holtforth, and Maramba's (2005) cognitive-behavioral assimilative integration and Stricker and Gold's (2005) assimilative psychodynamic therapy. It has been argued that assimilative integration does not represent its own integration pathway; rather, it serves as a prime example of how the above approaches are not mutually exclusive, and in clinical work, the distinctions among them are not so apparent (Norcross, 2005). Assimilative integration may be conceptualized as a bridge between technical eclecticism and theoretical integration, and this is often accomplished through the lens of common factors. One specific method for building this bridge is based on a theory of change involving change principles, such as those identified by Goldfried (1980) (see Boswell, Nelson, Nordberg, McAleavey, & Castonguay, 2010).

## *Theories of Change*

As previously described, a significant source of motivation for integration stems from clinicians' dissatisfaction with single-theory systems that do not fully explain, or cannot be applied to a diverse set of clients and presenting problems. Integration becomes an attempt to grapple with the inherent complexity of psychopathology and its treatment. An integrative theory of change can take many forms. However, two major, complementary systems have been advocated: principles of change, or core clinical strategies that cut across divergent theoretical orientations, and the transtheoretical model.

### CHANGE PRINCIPLES

Change principles are general guidelines of intervention that cut across different theoretical orientations. As described by Goldfried (1980), such principles (e.g., facilitation of a corrective experience, expectation that therapy can be helpful, participation in a therapeutic relationship, obtaining a new perspective of self and other, and opportunity

for repeated reality testing) are found at a level of abstraction between specific techniques and the theoretical models developed to explain why these techniques work. As argued by Goldfried (1980; Goldfried & Padawer, 1982), given this intermediate level of abstraction, change principles can be used as an implicit guide, or heuristic, for therapists in addressing a diverse number of clients and presenting problems.

It is important to note that these levels (theory, technique, and common change principles) interrelate. One who is technically eclectic cannot disregard theory, just as one who is a theoretical integrationist cannot disregard techniques, and common change principles would not be possible in the absence of both. According to Goldfried, techniques are parameters to facilitate change processes. For example, techniques such as interpretation and cognitive restructuring are viewed as particular manipulations of the same general principle of change: providing a new perspective. As argued by Castonguay (2000), however, principles or strategies of change need to be framed within an articulated theory of human functioning and change. Whether it is integrative or closely related to one of the four pathways described in this chapter, this theory is necessary to help clinicians decide when and how to foster a principle of intervention.

A complementary approach to understanding change processes has been the conceptualization of stages of change (see Prochaska & DiClemente, 2005). Individuals are assumed to progress through a series of stages as behavior is modified. These stages include: pre-contemplation, contemplation, preparation, action, and maintenance. Clinical experience and research evidence (e.g., Rosen, 2000) indicate that change processes (e.g., interventions and their mechanisms) are differentially effective, depending on the client's stage of change. For example, individuals judged to be in the contemplation stage are thought to benefit from interventions that raise their consciousness around problem behaviors, impacts, and other individuals; whereas individuals judged to be in the action stage are thought to benefit more from interventions that directly address behavioral processes (e.g ., counterconditioning and contingency management).

### Empirical Support
Despite being the focus of a large theoretical and clinical literature, empirical research on psychotherapy integration has been slow to progress.

However, evidence has begun to accumulate in recent years for factors that support and/or contribute to integration and treatments that fall under most of the major categories of psychotherapy integration (see Schottenbauer, Glass, & Arnkoff, 2005 for a comprehensive review).

A number of common factors have also received empirical support (see Weinberger & Rasco, 2007). The therapeutic relationship, for example, has been extensively studied across a number of treatment approaches and specific disorders and has been shown to be a robust and consistent predictor of positive treatment outcome (Castonguay, Constantino, & Grosse Holtforth, 2006; Martin, Garske, & Davis, 2000). Empirical support has also been found for client expectancies of treatment effectiveness (Baskin, Tierney, Minami, & Wampold, 2003; Constantino, Arnkoff, Glass, Ametrano, & Smith, 2011; Frank, Nash, Stone, & Imber, 1963; Howard, Kopta, Krause, & Orlinsky, 1986; Kirsch & Henry, 1977). Although the area of focus and the specific techniques used may differ between approaches, exposure is another common therapeutic factor with significant research support (Franklin & Foa, 2002; Heimberg et al., 1990; Roth & Fonagy, 2005).

In terms of eclecticism, the work of Beutler and colleagues has provided useful guidelines for prescribing specific types of interventions for certain types of clients (e.g., clients with high vs. low levels of reactance), leading to the development of systematic treatment selection and prescriptive psychotherapy. This system has accumulated the greatest empirical support for client–treatment matching (see Beutler et al., 2005 for a review).

Several treatments developed from an assimilative integration approach have garnered empirical support. For example, Greenberg and colleagues developed a process–experiential therapy (EFT) that has been tested in both individual and couples modalities. This therapy integrates process-directive and experiential interventions for specific client markers within a person-centered framework (Greenberg & Watson, 1998) and has been shown to be effective in the treatment of depression. Also from an assimilative integration perspective, in an effort to increase the effectiveness of a previously supported treatment, Castonguay designed and tested an integrative cognitive treatment for depression (ICT; Castonguay et al., 2004), which uses techniques from humanistic and interpersonal therapies to help repair alliance ruptures in traditional cognitive therapy, and has been shown to be superior to a waitlist control group

in a randomized trial for depression. In a replication trial, Constantino et al. (2008) found that clients in the ICT condition evidenced greater post-treatment improvement than did clients who received traditional cognitive therapy, and they also reported higher alliance and therapist empathy ratings across treatment. Other examples of integrative treatments with some empirical support include cognitive-behavioral assimilative therapy for generalized anxiety disorder (Newman et al., 2011; Newman, Castonguay, Borkovec, Fisher, & Nordberg, 2008), and mindfulness-based cognitive therapy for depression (MBCT; Segal, Teasdale, & Williams, 2002).

Examples of theoretically driven integrative treatments with empirical support also exist (e.g., Ryle's [2005] cognitive analytic therapy). Transtheoretical psychotherapy, based on the Transtheoretical Model (TTM; Prochaska & DiClemente, 2005), as mentioned, posits five stages of change (precontemplative, contemplation, preparation, action, and maintenance), with specific processes of change and related interventions to be used at specific stages. The transtheoretical psychotherapy model has been applied and tested in a variety of problem areas, for both health behaviors and mental disorders, and has been shown to be significantly related to change processes and outcome (Prochaska & DiClemente, 2005; Schottenbauer et al., 2005). Perhaps the most well-studied integrative treatment to date is Linehan's dialectic-behavior therapy (DBT) for borderline personality disorder. A number of process findings and efficacy studies have been conducted that lend support to this treatment and its assumptions regarding client change (Linehan, Cochran, & Cochran, 2001).

## Conclusion

Psychotherapy is a vibrant domain of theoretical, applied, and empirical knowledge that has benefited over more than a century from contributions of many mental health professions (e.g., psychology, psychiatry, social work). The vitality of this field is reflected by a large variety of psychotherapeutic treatments which, as we suggested in this chapter, can be clustered into four major contemporary orientations (psychodynamic, cognitive-behavioral, humanistic, and systemic) and one movement aimed at fostering different pathways of integration between them.

Each of the four specific systems of therapy is based on a model of human health and maladaptive functioning and each emphasizes a number of interventions and mechanisms of change to foster and explain the process of therapy. Consistent with an

argument made almost three decades ago (Goldfried, 1980), not many similarities can be found in the conceptual models underlying these four major systems. However, also in line with Goldfried (1980), a number of strategies or principles of intervention appear to cut across most if not all of them, such as the importance of establishing a therapeutic relationship and the facilitation of new and corrective experiences. As we described earlier, these principles of change, along with other common factors, reflect one of the current pathways of integration.

All of the contemporary approaches to psychotherapy, "pure-form" or integrative, have also generated research. The willingness of psychotherapy scholars to submit their claims of success (and some of their hypotheses regarding the process of change) to empirical investigation has provided the field with some solid scientific foundations. But we would like to argue that we are only witnessing the beginning of psychotherapy as a scientific approach. Consistent with its epistemological bases, and reflecting its predominance in the list of ESTs, CBT has demonstrated a longer and more systematic commitment to empirical scrutiny than other orientations. The lag between clinical (and/or theoretical) contributions and research support seems to be particularly wide within the integration movement (Castonguay et al., 2003). This is most unfortunate, not only because most therapists (at least in North America) currently identity themselves as integrationists, but also, as Goldfried (2009) recently reminded us, SEPI was created to facilitate the integration of different schools of therapy, as well as the integration of research and practice.

If attended to carefully, however, the unfortunate level of enthusiasm toward research in psychotherapy integration can actually address what has been viewed by many as the most important problem of the field of contemporary psychotherapy: The shaky state of the Scientist-Practitioner model upon which it is assumed to rest. As argued elsewhere, clinicians are more likely to pay attention to research findings if they are involved in research (Castonguay in Lampropoulos et al., 2002); and since a large number of clinicians are integrative in their approach, one could expect that their increased engagement in research will lead to more empirical attention given to integrative issues. To maximize the probability of this occurring, however, we would argue that clinicians need to be involved in all aspects of research—its design, implementation, and the dissemination of results (rather than simply being asked to hand out questionnaires or apply a treatment protocol,

as is too frequently the case in current research). In other words, for psychotherapy to reach its full potential as a scientific field, we believe that it should cease its almost exclusive reliance on what has been called "empirical imperialism" (Castonguay, in Lampropoulous et al., 2002), where researchers (most of them seeing only a few clients) dictate what to study and how to study it. A full and equal collaboration between researchers and clinicians, as aimed at by recent practice research networks (see Castonguay et al., 2010a, b), may instead be a more fruitful way to provide the field with clinically relevant and scientifically rigorous research.

# Evidence-based Practice in Clinical Psychology

Bonnie Spring *and* Kelly Neville

## Abstract

The Institute of Medicine identifies evidence-based practice (EBP) as a core competence for all 21st century health professionals (Greiner & Knebel, 2003). Psychology is a relative newcomer to the evidence-based movement, having just adopted EBP as policy in 2005 (www2.apa.org/practice/ebpstatement.pdf). Evidence-based practice is both a conceptual model and a process for basing clinical decision-making on the integration of research, client characteristics, and resource considerations. We describe the evolution of models of EBP across the health disciplines and discuss how the concepts and methods of EBP apply in clinical psychology. Psychologists' roles in relation to EBP are as creators, synthesizers, and consumers of evidence. We consider implications of EBP's adoption for clinical psychology training, and describe learning resources that support clinical psychologists in mastering EBP.

**Key Words:** Behavioral science training, clinical psychology, decision-making, empirically supported treatment, evidence-based practice

Evidence-based practice (EBP) is both a conceptual model and a process involving "the conscientious, explicit, judicious use of current best evidence in making decisions about the care of individual patients" (Haynes, Sackett, Gray, Cook, & Guyatt, 1996; Sackett, Rosenberg, Gray, Haynes, & Richardson, 1996). The conceptual model, elaborated below, depicts "three circles" or data streams to be integrated when making clinical decisions. One circle represents research; the second is client characteristics (including preferences and values); the third is resource considerations (including practitioner expertise or skills). Performing the EBP process, to be described later, entails carrying out a sequence of five steps. After assessing the presenting problem, the practitioner: (1) asks key questions, (2) acquires evidence to answer them, (3) appraises its quality and contextual relevance, (4) applies the evidence via shared decision-making that integrates client characteristics and resources, and, after reassessing, (5) analyzes outcomes and adjusts practice accordingly.

All major health professions have now endorsed EBP. The Institute of Medicine identifies EBP as a core competence for all 21st-century health professionals (Greiner & Knebel, 2003). Psychology is a relative newcomer to the evidence-based movement, having just adopted EBP as policy in 2005 (www2.apa.org/practice/ebpstatement.pdf). The purposes of this chapter are, therefore, to: (a) discuss how the concepts and methods of evidence-based practice apply to clinical psychology, (b) consider implications of EBP adoption for clinical psychology training, and (c) describe relevant learning resources for EBP.

## Rationale for Evidence-based Practice
### Health-care Quality

Since its first emergence in medicine a century ago, the evidence-based movement has been about finding ways to distinguish quackery from valid health practices. An important context for that aspiration is that it was not possible to identify legitimate

medical procedures until the start of the 20th century. Only then did the good outcomes of antiseptic surgery, vaccination, and public sanitation provide examples of scientifically derived practices that were differentiable from specious ones. During the preceding era when, as it were, one form of snake oil was as good as any other, numerous proprietary, for-profit schools of medicine did a brisk, profitable business in training physicians. Many date the onset of the evidence-based movement to the 1910 publication of the Flexner Report, which challenged the quality of that era's medical training. In work commissioned by the American Medical Association and the Carnegie Foundation, Abraham Flexner surveyed all 155 existing medical schools. His charge was to identify and root out those whose curricula failed to be based on science and rigorous clinical training. By 1935, as a result of the Flexner Report, more than half of all medical schools had been closed (Beck, 2004).

The EBP movement has continued to press for rational, systematic provision of high-quality care. To achieve that objective, the first problem that needed to be resolved was to find a basis on which to judge the quality of alternative care options. In Flexner's era, the best available science came from systematic observation and plausible inference based upon underlying pathophysiology. Then, in 1972, Archibald Cochrane, an epidemiologist well-known for population-wide descriptive studies, published a book championing the randomized controlled trial (RCT) as the most reliable, unbiased method to determine whether a treatment works. The RCT (discussed further later) is a kind of experiment in which patients are allocated randomly to experimental or comparable control treatments whose effects are contrasted on a limited number of pre-declared primary clinical outcomes.

Cochrane became convinced that the British National Health Service could be vastly improved if RCTs were used to test treatments, because that methodology would provide the most valid evidence about whether a treatment works (Cochrane & Blythe, 1989). That the RCT sits high on the hierarchy of best available evidence to determine the efficacy of treatments is a core tenet of EBP. In most accounts, the only form of evidence that sits higher still is a systematic review that examines the synthesized results of multiple RCTs. Named in Archibald's honor, the Cochrane Collaboration, launched in 1992, is an international voluntary organization dedicated to conducting systematic reviews of RCTs.

## Accountability and Health-care Policy

In his prescient 1972 book, entitled *Effectiveness and Efficiency: Random Reflections on Health Services*, Cochrane laid out an argument that equates EBP with accountable health-care policy. He noted that economic resources will always be limited. Therefore, he advocated, they should be divided equitably and spent wisely only on treatments that have demonstrable worth. The value of a treatment, he proposed, should be determined by high-quality RCTs, because this method provides the most valid, least biased estimate of treatment effectiveness. Health-care policy in the United Kingdom mirrors Cochrane's viewpoint (Norheim, 2008). When trying to determine whether a procedure should be paid for by the National Health Service (NHS), the United Kingdom's National Institute of Clinical Excellence (NICE) commissions a systematic evidence review. Treatments found effective are covered by NHS; those found ineffective are not. Those for which evidence is insufficient to make a determination are recommended to receive additional research.

In the United States, some health-care policy determinations are based upon synthesized research evidence. Systematic evidence reviews are used to determine coverage of specific procedures by Veterans Affairs/Department of Defense (cf., http://www.hsrd.research.va.gov/publications/esp/), Centers for Medicaid and Medicare (cf., www.cms.hhs.gov/mcd/ncpc_view_document.asp?id=7), and a growing number of private insurers. Increasing calls for transparency, equity, and accountability in health-care policies (Laupacis, 2006) may signal that evidence-based policy decisions will increase. Already, the National Guidelines Clearinghouse (www.guidelines.gov), sponsored by the Agency for Health Research and Quality, posts more than 2,000 EBP guidelines. Practice guidelines are sets of recommendations or principles to help health professionals and patients make decisions about screening, prevention, and treatment of specific health conditions. Only guidelines that are evidence-based are eligible for posting on the National Guidelines Clearinghouse website. To be considered evidence-based, a guideline must be documentably derived from a systematic literature search and review of existing scientific evidence published in peer-reviewed journals.

Upon what basis other than evidence can care be allocated? In the United States, at present, a driving force is market supply. For the past 30 years, it has been demonstrated repeatedly that U.S. medical expenditures increase in direct proportion to the medical resources that exist in a geographic area

(Wennberg, Fisher, & Skinner, 2002; Wennberg & Gittelsohn, 1973). Moreover, greater spending does not necessarily translate into better health outcomes (Wennberg, Fisher, & Skinner, 2002; Wennberg, Fisher, Stukel, & Sharp, 2004). Indeed, regions that spend more and provide more intensive services often achieve worse health outcomes than do areas that spend less and provide less care. International comparative data bear out the reality that greater U.S. spending on health care often fails to translate into better health. The United States currently spends $2 trillion on health care—far more than any other country (World Health Organization [WHO], 2000). Yet the WHO ranks the performance of the U.S. health system 37th relative to all other nations (WHO, 2000). The performance indicators are neither subtle nor abstract: the United States ranks only 26th among industrialized countries on infant mortality and 24th on life expectancy (WHO, 2000).

Clearly, there is a problem in accountability to the public for U.S. health-care investments. The root causes lie both in the current market drivers of health expenditures and in the lack of systems to establish rational spending. Influential, well-funded initiatives by drug and device manufacturers and guilds promote the use of expensive treatments. Often, there is a lack of good evidence about which treatments work best and most cost-effectively. Moreover, the process of deriving and disseminating such evidence can be fraught with political peril. When the federal Agency for Health Care Policy and Research (AHCPR) was formed in 1989, one of its goals was to formulate clinical practice guidelines by evaluating the outcomes of various diagnostic and treatment procedures. In 1994, the AHCPR issued evidence-based guidelines suggesting that most back surgery performed in the U.S. was unnecessary. The ensuing, well-orchestrated uproar by back surgeons led to the end of AHCPR's guidelines program in 1996 and to de-funding of the agency by Congress. When the Agency was reestablished in 1999, it was under a new name: the Agency for Health Research and Quality (AHRQ). Deletion of the word "Policy" from the name clearly disassociated AHRQ from an influence on U.S. health-care policies.

The U.S. Congress recently authorized new research on comparative effectiveness. Such research entails head-to-head comparisons to test which treatments work best and at what relative costs. A body of evidence on comparative effectiveness would potentially provide a basis for both evidence-based practice and policy. To become a firmly established component of evidence-based health care, psychological treatments need to be evaluated in comparative effectiveness research, both on their own and in combination with pharmacotherapy.

### Growth of the Evidence Base About Psychological Treatments

One of the greatest challenges faced by EBP stems from gaps in the research literature. Insufficiencies are especially stark in the areas of nondrug treatment and preventive care (Maciosek et al., 2006; Moyer et al., 2005). The U.S. Preventive Services Task Force (USPTF) has addressed this issue with particular eloquence. USPTF members note the disparity between the abundant quality and availability of evidence demonstrating the impact of behavioral risk factors for disease, versus the meager quality and availability of evidence supporting the efficacy, impact, and risk–benefit ratio of clinical preventive services to modify these risk factors (Maciosek et al., 2006).

For psychological treatments to become standard of care, it is critically important that trials testing their efficacy be included in systematic evidence reviews. Often, incomplete reporting or inadequacies in research design and implementation cause clinical trials of psychological treatments to be excluded from research syntheses (Spring, Pagoto, Knatterud, Kozak, & Hedeker, 2007). Lack of inclusion of psychological treatments in research syntheses deprives psychology's evidence of an opportunity to influence policy.

Policy-making bodies often find too little high-quality evidence to recommend for or against the delivery of many nonmedical interventions. Of course, absence of evidence is not the same as evidence of absence of an effect. Nonetheless, many policy-making bodies assign a grade of "I" for "insufficient evidence." Usually, a guidelines panel cannot advise for or against practices whose support is limited to expert consensus or less rigorous evidence (Moyer et al., 2005). The fact that systematic reviewers apply the same evaluative criteria when considering trials of medical and nonmedical treatments levels the playing field for psychological interventions. Inclusion in international databases like the Cochrane Library offers an opportunity to disseminate and enhance the evidence base for psychological interventions.

### Transdisciplinary Collaboration

The National Institutes of Health (NIH) Roadmap encourages transdisciplinary collaboration because

progress is often made at the interface of preexisting disciplines (Abrams, 2006; Zerhouni, 2005). Yet, even though boundary spanning has undeniable advantages, vast differences between disciplines in vocabularies and frames of reference can impede progress (Ruggill & McAllister, 2006). That EBP has come to provide shared vocabulary across health disciplines offers tremendous advantages for communication. Learning EBP vocabulary and methods affords psychologists invaluable opportunities to participate in transdisciplinary collaboration.

Just as future science will be increasingly transdisciplinary, future health-care teams will be increasingly interprofessional. The shared EBP framework supports jointly held foundational assumptions, vocabulary, and practice principles for psychologists who participate in interprofessional teams (Greiner & Knebel, 2003; Satterfield et al., 2009).

### Lifelong Learning

The methods of EBP were developed as a way to close the research-to-practice gap and foster lifelong learning (Institute of Medicine [IOM], 2001; Miller, 2005). A well-documented chasm exists between what research shows to be effective and what is done in usual clinical practice (Dubinsky & Ferguson, 1990; Field & Lohe, 1992; IOM, 2001). Often, practitioners continue to implement practices they learned during training (Isaacs & Fitzgerald, 1999; Turner, 2001), even when few of those practices were ever based upon evidence (Booth, 2007) and some have been supplanted by new evidence.

The research evidence base relevant to health professionals proliferates at an astonishing rate. There exist approximately 23,000 clinical journals that publish more than 2 million articles annually (Goodman, 2003). It is difficult to imagine how a practitioner could keep up to date with this primary literature (Koonce, Giuse, & Todd, 2004; Swinglehurst, Pierce, & Fuller, 2001). A growing set of databases of secondary, synthesized literature has evolved to meet practitioners' needs. One important resource already mentioned is the Cochrane Collaboration's online database of Systematic Reviews of health-care practices (www.cochrane.org). Other more clinically oriented resources to address practical questions are available online and/or on a hand-held device. These tools, based upon continually updated evidence reviews, offer pithy evidence synopses, clinical practice guidelines, and structured abstracts. Examples are UpToDate (www.uptodate.com), MD Consult (www.mdconsult.com), ACP Journal Club (www.acpjc.org), Clinical

Evidence (www.clinicalevidence.com), InfoPOEMS (www.infopoems.com), and Clin-eguide (www.clineguide.com).

At McMaster University in Canada, in the early 1980s, there developed a critical mass of faculty with an ambitious agenda: to close the research-to-practice gap. The group wrote many journal articles and books about how to keep up with and understand the research literature (Guyatt & Rennie, 2002; Haynes et al., 1986; McKibbon, Eady, & Marks, 2000). They wanted to develop a method that let practitioners find and apply evidence that answered their questions in real time, during the actual clinical encounter. The idea was to make it a habit to routinely ask questions, consult research, and integrate knowledge from three data strands (research, clinical experience, and the patient) when making clinical decisions. The rationale was that routinely performing such integration would overcome old, automatic decision-making biases and cultivate new learning. Gordon Guyatt coined the phrase "evidence-based medicine" to describe the EBP process. The new name represented a departure from the older term, "scientific medicine," which omitted the clinician's and patient's contribution to decision-making and overemphasized making inferences based on pathophysiology. The basic premise of EBP is that there should be no learning disjuncture between graduate school and subsequent professional life. While in school, just as afterward, engaging in EBP involves finding and implementing those practices that are supported by best available current research evidence. It is to be hoped that scientific progress supplants older best practices with newer and better ones, and that the evidence-based practitioner will continue to find the best evidence and upgrade respectively.

One can only marvel at the McMaster group's temerity. Just imagine trying to train practitioners to do library searching and critical appraisal of research at the bedside, in real time, before the advent of the internet. Having rapid access to the research evidence base at the point of care became critically important. Such access became feasible as the emergence of large electronic data sets brought library resources to the desktop. Perhaps not surprisingly, the McMaster group has played a key role in developing the health informatics that are needed to store, retrieve, manage, and use health information at the time and place that decisions need to be made. The science of informatics addresses resources, devices, and structures (e.g., treatment algorithms, practice guidelines, systematic evidence reviews,

and electronic medical records) that are needed to store, retrieve, manage, and use evidence at the point of care. The phrase, "evidence-based capitulation" is sometimes used pejoratively to describe practitioner reliance on filtered, synthesized evidence resources rather than primary research studies. However, use of such infrastructure is in keeping with the voluminous realities of contemporary science and practice.

## Framework for Evidence-based Practice
### Conceptual Models of Evidence-based Practice: The Three Circles

The root conceptual model for EBP depicts three interlinked circles (i.e., data strands) that must be integrated in order to determine optimal client care. Here, we review the evolution of EBP models in medicine, psychology, and allied health professions, leading to the most current transdisciplinary model. Research evidence has consistently remained a circle as the EBP models evolved over time. The contents of the other two circles have changed somewhat. Also varying has been the presence or absence of an interior circle that functionally ties the elements together into a three-legged stool.

#### EVIDENCE-BASED MEDICINE

The original three-circles model was introduced in 1992 as a "new paradigm" for the practice of medicine (Evidence-based Medicine Working Group, 1992) and a way to incorporate research findings into clinical care. Evidence-based practice was defined as "the conscientious and judicious use of current best evidence from clinical care research in the management of individual patients" (Haynes et al., 1996; Sackett et al., 1996). The proffered model depicted one circle labeled "clinical expertise" sitting atop and interlinked with two equal-sized circles labeled "research evidence" and "patient preferences." The intent of EBP was to promote an explicit and rational process for clinical decision-making that de-emphasized intuition and unsystematic clinical expertise, while highlighting consideration of best research evidence. Facetiously, EBP was contrasted with alternative forms of medical management: eminence-based, vehemence-based, eloquence-based, nervousness-based, and so forth (Isaacs & Fitzgerald, 1999). Evidence-based medicine explicitly de-emphasized the role of expert authority and endorsed a transparent, rational decision-making process that could be taught and applied by all clinicians. Placement of clinical expertise as the top circle was meaningful in stating the policy that clinical expertise may override research evidence under some conditions, as may patient preferences.

The first three-circles model was subsequently revised to address certain concerns (Haynes, Devereaux, & Guyatt, 2002a, 2002b). It can be noted, though, that the earlier model remains better-known and served as the template for the American Psychological Association's (APA) 2006 EBP conceptualization. The original 1996 (Haynes et al., 1996) three-circles model offered a vague definition of clinical expertise and no guidance about how to address discrepancies between the research evidence and either patient preferences or clinical opinion. The updated model attempted to address these concerns. A "clinical state and circumstances" circle replaced the original circle containing clinical expertise. Instead, clinical expertise was depicted as an interior circle that tied together evidence, patient preferences, and clinical state. Retaining clinical expertise as the central integrating circle expressed respect for the practitioner's pivotal role. Notably, clinical expertise was defined in terms of skill in performing the EBP process; that is, the abilities to elicit, appropriately appraise, and ultimately integrate the three potentially disparate sources of data (Haynes et al., 2002a, 2002b).

Proponents of EBM have always been clear in stating that all three EBP circles are of equal importance. Research is seen as a necessary but not sufficient component of clinical decision-making. However, the vast majority of the literature and teaching on EBM has addressed critical appraisal of published research. One respected resource is *The Users' Guides to the Medical Literature* series, first released as a series of articles in the *Journal of the American Medical Association* and then in online and book versions. The series addresses 25 separate topics in appraising and applying the results of studies focused on questions about therapy, diagnosis, prognosis, and harm. For teaching EBP in medicine, the main text is a small coat-pocket–sized book called *Evidence-Based Medicine: How to Practice and Teach EBM*. Lead-authored by David Sackett through its second edition (Sackett, Strauss, Richardson, Rosenberg, & Haynes, 2000), the third edition of the volume is now led by Sharon Strauss (Strauss, Richardson, Glasziou, & Haynes, 2005).

Certain principles are expressed as core tenets of EBP as it has been taught in medicine (Guyatt & Rennie, 2007; Strauss et al., 2005). The first principle is that of the hierarchy of evidence. The higher-up

a research methodology is ranked on the evidence pyramid, the more robust and closer to the truth its results are considered to be. Most versions of the hierarchy for treatment questions place systematic reviews of multiple RCTs at the top. Single RCTs come next, as the RCT design is considered the most valid way of removing bias and contrasting comparable groups. Lower down come observational studies without randomization, and at the bottom of the hierarchy come anecdote and opinion.

A second principle of EBM is that all clinical decisions need to attend to the preferences and values of the informed patient. Understanding of patient preferences has continued to be underdeveloped in EBP, but is now benefiting from work ongoing in the field of shared decision-making (Strauss et al., 2005). A third principle endorses an EBP process: a clear sequence of steps to be followed in integrating research into the care of a patient (Strauss et al., 2005; Bhandari & Giannoudis, 2006).

### EVIDENCE-BASED PRACTICE IN OTHER HEALTH DISCIPLINES

Following after medicine (Sackett et al., 1996), the EBP movement was embraced by nursing (Craig & Smyth, 2002), social work (Gibbs, 2003), and public health (Brownson, Baker, Leet, & Gillespie., 2003). Each discipline retained research evidence as one of the three circles, but otherwise adapted the model to its own context and introduced improvements (Satterfield et al., 2009). Evidence-based nursing moved beyond EBM by increasing the integration of patient experiences and preferences into clinical decision-making. Partly because there is a dearth of RCT evidence in nursing, EBP in nursing gave greater emphasis to qualitative data, patient satisfaction, QI data, and cost-effectiveness (Newhouse, Dearholt, Poe, Pugh, & White, 2007; Stetler, 2001; Titler et al., 2001).

Contextual influences on EBP have received heightened attention in recent social work models of EBP (cf., Regehr, Stern, & Shlonsky, 2007). Social workers' roles in management and policy in addition to clinical practice draw them into intimate contact with external constraints and facilitators. Consequently, the EBP conceptualization emphasizes sensitivity to surrounding socio-historic, political, economic, organizational, and community influences.

Public health's model of EBP focuses on the well-being of a population rather than an individual. The prevailing model, put forward by Kohatsu,

Robinson, and Torner (2004), is adapted from the thinking of Sir Muir Gray (1997), Chief Knowledge Officer of Britain's National Health Service. In public health's EBP model, the patient circle became population needs, values, and preferences; the research circle was retained. However, as in nursing, few RCTs are available to guide front-line public health practice, resulting in greater reliance on observational studies, time series analyses, and quasi-experiments. Finally, the third circle became resources. That revision acknowledges the reality that resource considerations usually emerge front and center in public health decision-making. Especially in the constraint-ridden world of public health, where overtaxed systems are often insufficient to meet population needs, resources set constraints on an intervention's feasibility.

### TRANSDISCIPLINARY MODEL OF EVIDENCE-BASED PRACTICE

In 2006, the NIH Office of Behavioral and Social Science Research (OBSSR) commissioned a 5-year project to harmonize the EBP approach and support communication and collaboration across health disciplines. The resulting multidisciplinary Council and Advisory Board for Training on Evidence-Based Behavioral Practice (EBBP), chaired by the first author, includes EBP experts from medicine, nursing, psychology, social work, public health, and library sciences (www.ebbp.org). The transdisciplinary model of EBP, depicted in Figure 7.1, incorporates the most important advances made within each profession and reflects an emphasis on shared decision-making.

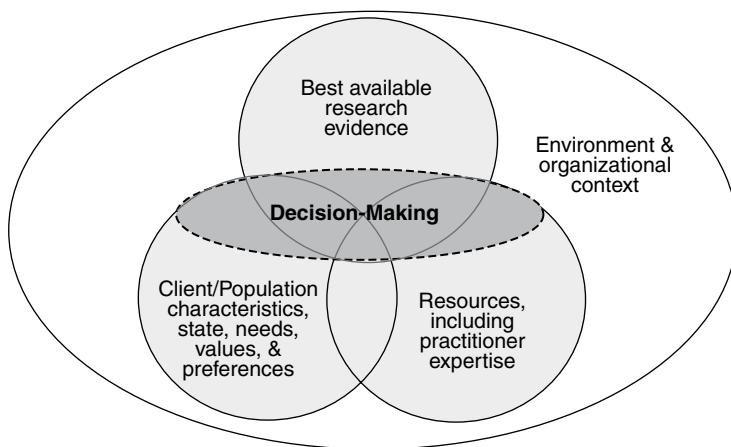
The transdisciplinary EBP model depicts three data streams to be integrated when deciding upon a course of action: evidence, client characteristics, and resources. Best available scientific evidence remains one of the three circles. Client values, preferences, and characteristics remain a second circle. Reflecting a conceptual advance from public health, the third circle is resources, which includes practitioner expertise. Decision-making is the central concept of the model and the action that ties the three data streams together in EBP. The transdisciplinary EBP model is grounded in an ecological framework (McLeroy, Bibeau, Steckler, & Glanz, 1988) that suggests a need to understand the environmental and organizational context for a problem and address influences at multiple levels. Consequently, the model depicts the decision-making process in the surrounding environmental and institutional context that frames it.


**Figure 7.1** Elements that need integration in evidence-based practice

*Best Research Evidence*

Evidence is comprised of research findings derived from the systematic collection of data through observation and experiment, and the formulation of questions and testing of hypotheses. What constitutes best research evidence depends upon the question needing to be addressed (Sackett & Wennberg, 1997). For example, for questions about etiology or prognosis, the optimum research design is often a longitudinal cohort study. For questions concerning the efficacy and effectiveness of treatments, the research design least prone to bias or error is the RCT. Topping the evidence pyramid for a question about treatment is the systematic review, which synthesizes the findings from many treatment trials (Oxford Center for Evidence Based Medicine, 2001). Recently there have been renewed calls for contextualized research evidence that is directly relevant to the specific patient and practice context (Weaver et al., 2005; Westfall, Mold, & Fagnan, 2007). Accordingly, some presentations of the evidence hierarchy place at the apex of the evidence pyramid an $N = 1$, single-case experimental design study that tests the treatment of interest with the target patient (Guyatt et al., 1986; Mahon et al., 1996).

*Resources*

The resources circle depicts the skills and infrastructure support that are needed to offer EBPs. Resources include the physical, technological, personnel, and financial assets needed to deliver treatments (e.g., space, time, technological support, finances including insurance reimbursement, and expert practitioners trained in EBP). Other needed resources may involve institutional endorsement by higher administration and agreement from other system components.

Universally, resources are a variable that factors into evidence-based decisions. The most efficacious treatment is irrelevant to any but theoretical EBP if there is no trained practitioner accessible to deliver treatment or no resources to pay. The creation of resource-sensitive practice guidelines is a new development in EBP (cf., Fried et al., 2008). Such guidelines review the quality of evidence supporting alternative practice recommendations that fit the resources available. Decision-makers can use the guideline to gauge the level of intervention intensity that makes best use of accessible infrastructure, human capital, and financial wherewithal.

The transdisciplinary EBP model incorporates practitioner expertise within the broader circle that depicts needed resources. In earlier models of EBP, the circle named practitioner expertise generated the greatest controversy and underwent several revisions (Spring et al., 2005). In part, the difficulty reflected ambiguity in medicine's original EBP model (Haynes et al., 1996), which sometimes led practitioner expertise to be misconstrued as opinion or unquestioned intuition (McFall, 1991; Meehl, 1973; Thornton, 2006). Later versions of the EBP model in medicine (Haynes et al., 2002a;) operationalized expertise as skill in performing the steps of the EBP process (e.g., asking questions, acquiring evidence, critically appraising research), etc.

In the transdisciplinary EBP model, practitioner expertise entails four categories of skills:

1. *Assessment skills* pertain to the appraisal of client characteristics, problems, values and expectations, and environmental context. Competency in assessment also applies to the practitioner's ability to assess in an unbiased manner his or her own level of expertise to

implement techniques and the outcomes of those techniques once implemented.

2. *Evidence-based practice process skills* involve competency at performing the steps of the EBP process: ask well-formulated questions, acquire best available research evidence, appraise evidence for quality and relevance, apply evidence by engaging in shared decision-making with those who will be affected, analyze change, and adjust practice accordingly.

3. *Communication and collaboration skills* entail the ability to convey information clearly and appropriately, and to listen, observe, adjust, and negotiate as appropriate to achieve understanding and agreement on a course of action.

4. *Engagement and intervention skills* involve proficiency at motivating interest, constructive involvement, and positive change from individuals, groups, organizations, communities, and others who may be affected by health decisions. Interventions vary in the degree of training, experience, and skill required to implement them competently.

### Client Characteristics, State, Needs, Values and Preferences

Except for single-case studies, research evidence describes the average responses of individuals or groups. The core challenge addressed by EBP is how to apply the averaged data to an individual client. The evidence needs to be appraised in relation to the particular circumstances at hand. Client characteristics are one key set of contextualizing factors that need to be taken into account. Relevant client attributes include state and trait variation in condition, needs, history of treatment response, values, and preferences. To decide whether available research evidence is truly relevant to the client, a judgment must be made about the comparability between the client and the study population. Some tailoring (e.g., literacy level of materials) can often enhance treatment feasibility and acceptability, without undermining fidelity to core treatment elements that make a treatment effective (National Cancer Institute, 2006).

Client preferences warrant special mention as a contextualizing variable. Preferences are the lynch-pin of shared decision-making, but are also the least-developed aspect of the EBP model. The rationale for shared decision-making is to engage patients more fully in self-managing their own wellness and health care. For shared decision-making to become a reality, there are two needed preconditions. One is

departure from a paternalistic care model, in which the provider makes decisions on the patient's behalf. The other is progress toward a more culturally informed shared model of care. The idea is for providers to respect and help patients clarify their own values and treatment preferences.

The need to systematize an approach to patient preferences is inescapable and complex. How patients weigh out the relative risks and benefits of treatment alternatives is personally distinctive, subjective, and often not previously considered by the patient. Effective deliberation also requires information that may be unknown to the patient, such as the range of treatment alternatives, including no treatment, and their potential inconveniences and risks. For many psychological conditions, patients need to determine whether they prefer to be treated pharmacologically, psychosocially, or both. The availability of insurance coverage for specific treatments also factors in, as do such logistical considerations as geographic access to trained therapists, scheduling, transportation, and child care.

Evidence-based practice has done much to highlight the importance of shared decision-making in the health-care delivery process (Edwards et al., 2005; Gravel, Legare, & Graham, 2006; Krahn & Naglie, 2008). Engaging clients in decision-making that acknowledges their preferences is justifiable on sociopolitical grounds of equity. Shared decision-making is also justified on evidentiary grounds because of the association between shared decision-making and improved health outcomes (Say & Thomson, 2003; Spring, 2008).

### EVIDENCE-BASED PRACTICE IN PSYCHOLOGY

The need to align psychology with other health professions led the APA to form an Evidence-Based Task Force in 2005. The Task Force's definition of EBP modeled the original three-circles model from medicine (APA Presidential Task Force on Evidence-based Practice, 2006; Haynes et al., 1996). However, although the APA Task Force acknowledged that some research designs are better than others, they did not endorse a hierarchy of evidence. The APA did improve upon the original three-circles model in two primary ways. First, the Task Force proposed a number of competences (e.g., assessment, diagnostic judgment, systematic case formulation, and treatment planning) to operationalize clinical expertise. Second, as incorporated in the Transdisciplinary EBP model, they elaborated the patient preference circle to include patient characteristics, values, and context.

In addition to noting relevant contextual factors (e.g., social support), they outlined a comprehensive portfolio of personal and sociocultural factors germane to clinical decision-making (e.g., age, gender, ethnicity, social class, religion, income, functional status, readiness to change, and developmental history).

It is ironic that psychology is among the last health professions to adopt the EBP framework, because clinical psychologists first contemplated a version of EBP before the movement took root in medicine. In fact, clinical psychologists actually proposed an approach to EBP a year earlier than the McMaster group published their influential initial papers on EBM (Haynes et al., 1996). In 1995, the American Psychological Association's Society of Clinical Psychology (Division 12) released the first report of its Task Force on Promotion and Dissemination of Psychological Procedures, chaired by Dianne Chambless (Chambless et al., 1996). Division 12's Task Force aimed to establish standards of evidence that could be applied to select which psychological treatments warranted inclusion in psychology training programs. Treatments identified as having strong research support were initially called *empirically validated*; ultimately, they were called *empirically supported treatments* (ESTs). In transparently publishing its evidentiary criteria,

clinical psychology anticipated the general policy of critical appraisal that EBM would later implement to select best practices for endorsement in treatment guidelines.

Table 7.1 shows how the 1998 Division 12 Task Force classified different levels of research support for various psychological treatments (Chambless et al., 1998). Those evaluative criteria remain unchanged in a 2008 update recently published online at www.psychology.sunysb.edu/eklonsky-/division12. Treatments judged to be "well-established" or "probably efficacious" require a treatment manual, specification of participant characteristics, and replication by an independent investigator. The "strong evidence" that is considered to warrant designation as a "well-established treatment" consists of two or more good group experiments showing superiority or equivalence of a treatment to a matched intervention that controls for attention and expectations. The Division 12 website now improves upon the original published criteria by clarifying that an RCT is what is meant by a "good group design." Criteria for judging the quality of an RCT are not specified. Also, in addition to RCT evidence, the Task force accepts as strong evidence nine single-case experiments. To qualify as "probably efficacious" the Task Force requires "modest evidence." The Task Force characterizes modest research evidence as involving

**Table 7.1  Criteria for empirically validated treatments**

Well-established Treatments

I. At least two good between-group design experiments demonstrating efficacy in one or more of the following ways:
    A.  Superior (statistically significantly so) to pill or psychological placebo or to another treatment.
    B.  Equivalent to an already-established treatment in experiments with adequate sample sizes.
*OR*
II. A large series of single-case design experiments ($n > 9$) demonstrating efficacy. These experiments must have:
    A.  Used good experimental designs and
    B.  Compared the intervention to another treatment as in IA.
*Further Criteria for Both I and II:*
III. Experiments must be conducted with treatment manuals.
IV. Characteristics of the client samples must be clearly specified.
 V. Effects must have been demonstrated by at least two different investigators or investigating teams.

Probably Efficacious Treatments

 I. Two experiments showing the treatment is superior (statistically significantly so) to a waiting-list control group.
*OR*
 II. One or more experiments meeting the Well-Established Treatment Criteria IA or IB, III, and IV, but not V.
*OR*
III. A small series of single-case design experiments ($n > 3$) otherwise meeting Well-Established Treatment

From Chambless, D. L., Baker, M. J., Baucom, D. H., Beutler, L. E., Calhoun, K. S., Crits-Cristoph, P., et al. (1998). Update on empirically validated therapies, II. *The Clinical Psychologist, 51*(1), 3–16. Reprinted with permission.

well-designed experiments lacking independent replication, comparison to a waitlist (rather than attention control) comparison group, or support from fewer than nine single-case experiments.

The 1996 Task Force identified 18 treatments as "empirically supported" (Chambless et al., 1996). Based on a later report, 16 ESTs were then widely disseminated to clinical psychology training programs across the country (Chambless et al., 1998). The number of psychological treatments that the Division 12 Task Force considers empirically supported has more than doubled in the past decade. The Society of Clinical Psychology website now lists 38 treatments as having strong support.

The ESTs generated enthusiasm, and they also stimulated controversy (Norcross, Beutler, & Levant, 2005; Spring et al., 2005, Wampold, 2001). Many objected to a perceived neglect of clinician variables, a criticism that had also been leveled against "scientific medicine" (Sackett et al., 1996; G. Guyatt, personal communication, 2008). To some, the provision of therapy based on research-tested treatment manuals gave the appearance of "cookbook" therapy. Others noted a lack of evidence that specific psychotherapies work best for specific disorders (Luborsky, Singer, & Luborsky, 1975). They suggested that nonspecific therapeutic elements, such as positive expectations and a therapeutic alliance, account for the efficacy of most psychological treatments (Wampold, 2001). Bias was seen in the fact that most of the originally selected ESTs were grounded in either a cognitive or behavioral theoretical orientation. Some even argued that psychotherapy could not be appropriately studied via an RCT design because results could not be generalized to real-world practice (Goldfried & Wolfe, 1996). Throughout the debate, the elephant in the room was fear that EBP really meant cost-cutting and restriction of clinician autonomy (Spring et al., 2005; Pagoto et al., 2007).

As the 21st century arrived, most health professionals faced shrinking reimbursements on the one hand, and increased demands for care quality and accountability on the other. Concerns about curtailment of practice were ubiquitous and reasonable under such circumstances. Many professions responded by formulating clinical practice guidelines that justified reimbursement of best practices by documenting the evidence that established their efficacy. Psychology, however, took a very different approach. Given ongoing controversy about ESTs, the APA opted for an unusual solution. First, an APA Task Force drew an idiosyncratic verbal distinction between "practice guidelines," defined as addressing the general conduct of practitioners, and "treatment guidelines," defined as providing recommendations about interventions to be offered to patients (APA, 2002). Second, the Association formulated policy stating that the APA would formulate practice but not treatment guidelines. Instead, APA's Task Force proposed criteria for evaluating the treatment guidelines developed by other organizations (APA, 2002).

It is interesting to compare the pace of adoption of EBP policy in psychology to that in other disciplines. Certainly, controversies also surrounded adoption of EBP in other health professions (Sackett et al., 1996; Spring et al., 2005), but they resolved more quickly. The core objection was the same in most fields: the argument that science should not dictate practice (Goldfried & Wolfe, 1996; Wampold, 2001; Bohart, 2005). Medicine responded to this critique by renaming their approach "evidence-based medicine" rather than "scientific medicine," and by supplementing research data with input from clinician and patient. In contrast, clinical psychology has, until very recently, retained an EBP model that includes only one circle: research. Accordingly, many students of clinical psychology continue to reduce the concept of EBP to ESTs (Luebbe, Radcliffe, Callands, Green, & Thorn, 2007).

In wondering whether the exclusive focus on ESTs has helped or hindered the progress of EBP in clinical psychology, we suspect that the answer is, "both." A tremendous accomplishment of Division 12's Dissemination Task Force was to achieve the uptake of ESTs into the curricula of all accredited U.S. training programs in clinical psychology. Increased practical skill training in EST delivery remains needed (Weissman et al., 2006), but at least didactic coverage of ESTs has been extensively incorporated into graduate training. Psychology's success in disseminating research-supported practices into the graduate curriculum outstrips that of most other health professions. Another achievement probably brought about by focusing on ESTs has been to stimulate growth of the evidence base for psychological treatments. That success, suggested by a doubling of the number of efficacious ESTs in less than 10 years, can be considered a major accomplishment. Its importance should not be underestimated, particularly since insufficiencies in the evidence base represent one of the most significant impediments to EBP in all health disciplines.

On the other hand, there appear also to have been some drawbacks associated with an exclusive focus on research as the sole consideration for EBP.

Drawing a sharp bifurcation between research data and other kinds of data from the clinical encounter may have heightened polarization between more science-oriented and more practice-oriented constituencies of clinical psychologists. A consequence is that our field has now spawned two separate accrediting bodies for clinical psychology training programs. Clinical scientist training programs will soon seek accreditation through the Academy of Psychological Clinical Science, whereas scientist-practitioner and practitioner-scientist training programs will continue to seek accreditation through the APA. Perhaps in no other health discipline has a cultural gap between researchers and practitioners emerged quite so strongly.

### Psychologists' Roles in Evidence-based Practice

As depicted in Figure 7.2, psychologists have three main roles in relation to EBP. In each role, the psychologist is chiefly a consumer of data from some EBP circles and a contributor to others (Spring, 2007). First, as primary researchers, psychologists contribute directly to creating the evidence base. They design, conduct, analyze, and report research that characterizes the risk factors, course, and causal influences on a wide range of health problems. Psychologists validate instruments to assess clinical conditions, and they develop and test treatments to alleviate psychological and other health problems. The evidence that psychologists create as primary researchers is used by both systematic reviewers and practitioners.

Second, as systematic reviewers, psychologists use primary research that has been created by others to create syntheses that are used by clinicians and policy-makers. They locate the primary research that addresses a practical question, and they critically appraise, extract, and synthesize the information to provide an answer. Systematic reviewing is itself a sophisticated and evolving form of research methodology that is increasingly becoming the basis for health policies.

Third, as clinicians, psychologists have the most challenging role in EBP. The clinician extracts and uses data from each of the three circles of EBP.

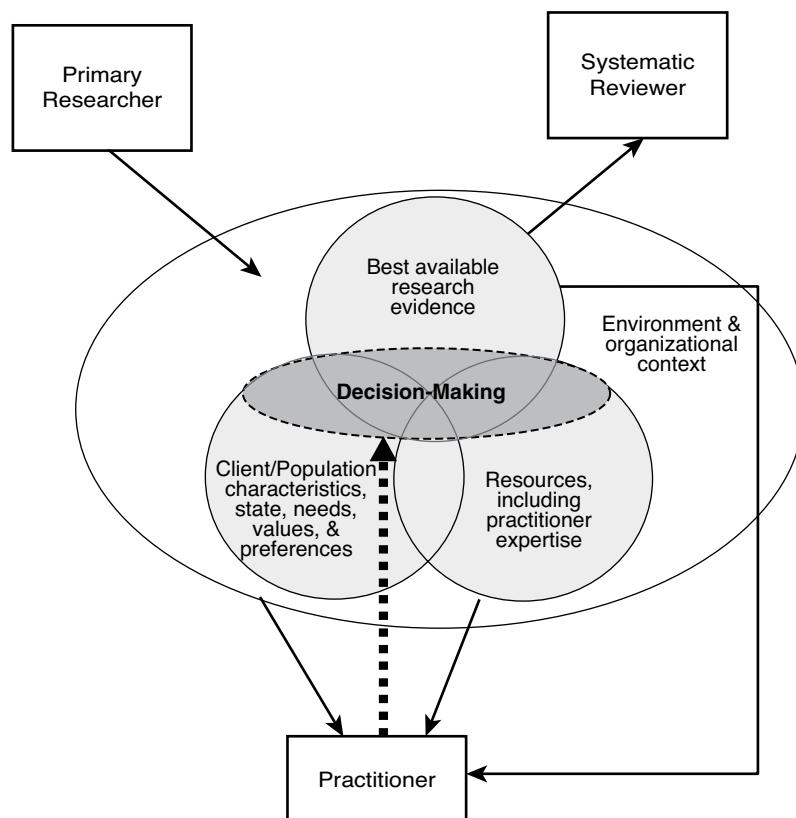

**Figure 7.2** Psychologists' roles in evidence-based practice

Clinicians are research consumers: they access research evidence and appraise its quality and relevance for their context. In the practitioner role, the psychologist also acquires and parses data about client characteristics, including developmental course, treatment response history, needs, values, and preferences. Additionally, the psychologist as clinician assesses available resources, including his or her own personal training and skill in delivering relevant ESTs.

## Training for Evidence-based Practice

Several forms of learning will enhance psychologists' abilities to participate fully in the EBP movement as creators, synthesizers, or consumers of research evidence (Spring, 2007). The discussion below describes content not presently well-covered in the clinical psychology curriculum and suggests available resources that might be considered to provide coverage.

### Primary Research: Evidence Creation

As noted earlier, the RCT design is considered the gold standard for testing whether a treatment works. Increasingly, RCTs are aggregated in systematic reviews and analyzed to determine coverage policy. For psychological treatments to become standard of care, it is critically important that the RCTs testing them be included and fare well in systematic evidence reviews. Often, incomplete reporting or inadequacies in research design and implementation causes behavioral clinical trials to be excluded from research syntheses (Davidson et al., 2003; Spring et al., 2007). Lack of inclusion in research syntheses deprives psychology's evidence of an opportunity to influence policy.

#### DESIGN AND IMPLEMENTATION OF THE RANDOMIZED CONTROLLED TRIAL

A number of key features define an experiment as an RCT. First, in an RCT, participants are allocated randomly to the active experimental treatment or to an inactive control condition that is comparable in important respects (e.g., credibility, attention, therapist contact, and incentives). A second key feature to prevent selection bias is *allocation concealment*. It is critically important that both clinicians and patients remain in the dark about upcoming treatment assignments. If the allocation sequence can be deciphered, the researcher's decision to accept or reject a study candidate or the participant's decision to give informed consent can be influenced in a manner that subverts randomization (Schulz & Grimes, 2002).

A third feature that defines an experiment as an RCT is that only a small number of primary outcomes (e.g., between one and three) on which the treatment's effects will be measured is selected and declared in advance of beginning the trial. Registering these primary outcomes in the database at www.ClinicalTrials.gov (a service of the U.S. NIH) serves to protect the evidence base against findings that capitalize on chance. Otherwise, when a treatment fails to show predicted effects on primary outcomes, there may be temptation to "fish" or "cherry-pick." The dangers being addressed are the joint product of publication pressure upon researchers and editorial bias imposed by journals more inclined to publish positive than null results. Preselection and advance declaration of primary outcomes guards against trial reporting of successful secondary outcomes rather than the primary outcomes that were preselected as the treatment's proving ground.

A fourth property of RCTs is *blinding*. Under ideal double-blind conditions, both patients and interventionists are kept in the dark about which treatment the patient has received. Since double-blinding is rarely feasible (or even appropriate) in trials of psychological treatments, alternative procedures are usually adopted. For example, the desirability and credibility of the experimental and control treatments is equated to the extent possible, and the outcome is assessed by independent assessors who are kept blind to treatment assignment. A fifth property of RCTs concerns the data-analytic policy of *intent to treat*. Under intent-to-treat analysis, patients are retained and analyzed in the treatment to which they were randomized regardless of whether they received the intended treatment.

It is very rare for clinical psychologists to receive graduate training specifically devoted to clinical trial methodology. Students learn group comparison methods in coursework on experimental design and statistics. Consequently, it is natural for psychologists to conceptualize RCTs as simple experiments (as they are in many respects). However, the experimental tradition in psychology derives from laboratory research that affords very tight control over the experimental stimulus and most extraneous sources of variation (Maher, 1968; Wilson, 1981). Stimulus intensity and duration, diet, time of day, presence of others, and the like can all be regulated. The experimental manipulation is often simple and able to be characterized exactly. Measurement of the outcome usually occurs after a brief assessment interval, and there are ordinarily few or no missing data.

Contrast that with the usual scenario in a trial comparing a psychological treatment to a control intervention. Rather than being a loud noise or a short audiotaped message or a film, the experimental stimulus now becomes a complex intervention that transpires between two or more human beings over an extended period of time. The very first challenge is to establish whether the experimental stimulus even occurred—a task more challenging than it sounds. The question is addressed by coding directly observed or recorded treatment sessions to measure *treatment fidelity* (whether the intended treatment was delivered as planned).

If one considers an RCT to be identical to a laboratory experiment, the rationale for intent-to-treat analysis policy is especially challenging to understand. In a laboratory experiment, if a mishap occurs and an animal escapes or a human quits the study, it is logical to replace the lost case. Because the missing subject was not exposed to either intervention condition, including the person in the analysis would appear to compromise the internal validity of the experiment. Viewed from that perspective, a "completer analysis" that retains only those participants exposed fully to their assigned treatment conditions would seem the most valid approach. Perhaps that mistaken assumption explains why trials of psychological interventions reported in the behavioral research literature continue to show deficiencies in intent-to-treat analysis and in other aspects of the handling of missing data (Pagoto et al., 2009; Spring et al., 2007).

Epidemiologists understand RCTs as tests of whether a treatment constitutes sound public policy. Framed in that manner, a treatment that is declined or deserted in midstream by many individuals is a poor treatment, regardless of whether it has outstanding efficacy among the subset that continues to adhere. From a public health perspective, the treatment's viability needs to be evaluated by considering outcomes for the entire group of people that was assigned to receive it. Hence, the policy, "Once randomized, always analyzed."

## RESOURCES FOR LEARNING ABOUT RANDOMIZED CONTROLLED TRIALS

A number of good textbooks on randomized controlled trials exist. These include Steven Piantadosi's (2005) Comprehensive *Clinical Trials: A Methodological Perspective* (2nd ed.), S. J. Pocock's (1984) *Clinical Trials: A Practical Approach,* and the paperback *Fundamentals of Clinical Trials* by Lawrence M. Friedman, Curt D. Furberg, and David L. DeMets (1999).

An excellent in-person training opportunity is the annual 2-week Summer Institute for Randomized Clinical Trials Involving Behavioral Interventions, sponsored by OBSSR. Also available and helpful are the many scales that have been published to evaluate the quality of clinical trials (cf., Jüni et al., 2001). Examining these quality scales when designing and executing an RCT enables a trialist to begin with the end in mind. Remaining mindful of the criteria that systematic reviewers will use to determine whether a trial passes threshold for inclusion in a research synthesis can improve the quality of the RCT.

## REPORTING OF RANDOMIZED CONTROLLED TRIALS: THE CONSORT STATEMENT

It is not enough for an RCT to be designed and conducted well. It also needs to be reported well and transparently, so that it can influence practice and policy. A useful tool to support reporting of RCTs was created by an international group of epidemiologists, statisticians, journal editors, and trialists known as the Consolidated Standards of Reporting Trials (CONSORT) Group. The CONSORT Statement and reporting guidelines (Altman et al., 2001; Moher, Schulz, & Altman, 2001) have been endorsed by many leading journals in the medical (e.g., *The Journal of the American Medical Association [JAMA], The Lancet*) and behavioral sciences (e.g., *Journal of Consulting and Clinical Psychology, Health Psychology, Annals of Behavioral Medicine*). The CONSORT Group's website (www.consort-statement.org) provides a checklist of 22 items that should be reported when presenting an RCT, and a flow diagram that depicts participants' progress through the trial. The aim of the CONSORT statement is to standardize and make more transparent the research process, so that evidence users and synthesizers can clearly evaluate validity and relevance for their context.

Several checklist items are of particular relevance to psychologists because they represent areas in which our reporting of trials is often incomplete (Pagoto et al., 2009; Spring et al., 2007; Stinson, McGrath, & Yamada, 2003). One example involves specifying the study eligibility criteria and their impact on enrollment (important for appraising external validity). A second is describing how the sample size was determined. A third involves detailing how the randomization sequence was generated,

concealed, and implemented. A fourth concerns describing whether any blinding was implemented and how its success was evaluated, including blinding assessors of the study outcomes. A fifth area in which reporting of psychosocial intervention trials often falls down involves specifying, in advance, clear primary and secondary outcomes, so that a priori hypothesis testing can be discriminated from subsequent cherry-picking. Finally, improvement is needed in providing enough information about the number of cases analyzed in each group to enable readers to tell whether comparisons were conducted on an intent-to-treat basis. Exposure to the CONSORT statement is useful for clinical psychologists, regardless of whether they wish to appraise, create, or synthesize research evidence about the effectiveness of treatments.

### SYSTEMATIC REVIEW: EVIDENCE SYNTHESIS

As noted, systematic reviews are an increasingly vital part of the infrastructure needed to perform EBP. Some scientific journals (e.g., JAMA) no longer accept traditional narrative literature reviews, but continue to welcome systematic evidence reviews. The distinctive features of a systematic review stem from the care that is taken to avoid bias in gathering and summarizing the literature (Dickersin, 2002; Pai et al., 2004). One key tool is the prespecified search protocol. The protocol states the question to be answered by the review. The question is phrased in PICO language, which specifies the target *P*opulation, *I*ntervention, *C*omparison, and study *O*utcomes (primary and secondary dependent variables). Also specified are clear criteria for including or excluding studies, and all key words and terms that will be used to guide the search.

To minimize bias, the approach in conducting searches for a systematic review is to be as inclusive and transparent as possible. The search protocol declares which databases will be examined and by which search engines. The protocol also states whether gray literature (e.g., unpublished manuscripts, conference proceedings, etc.) will be scrutinized and whether articles written in certain languages will be filtered out. The selection of databases to be searched has important practical and substantive implications. Key indexing terms differ across databases (e.g., PubMED uses MeSH terms; psycINFO uses the Thesaurus of Psychological Index Terms). Additionally, EMBASE (Medline's European counterpart) and CINAHL (a database used extensively by nurses and other allied health professionals) include many journals that are not included in either MEDLINE or psycINFO. As compared to Medline or psychINFO, searching EMBASE, the Cochrane Database of Systematic Reviews, and the Cochrane Controlled Clinical Trials Registry is more likely to yield reports of null or negative findings which can, in turn, influence a review's conclusions (Sampson et al., 2003). The Cochrane Database of Systematic Reviews and the Cochrane Controlled Clinical Trials Registry may also yield unique citations, and sometimes unpublished studies, identified by Cochrane reviewers. The assistance of a trained librarian can be invaluable throughout the search process.

Once the initial pool of articles has been assembled (usually at least several hundred), two or more raters sort the articles for relevance and quality using prespecified criteria. Most rating scales for trial quality offer separate items to code internal validity, external validity, and analytic quality. Of the many available rating scales for methodological quality, Jadad et al.'s (1996) is the most widely used, but its emphasis on double-blinding is inappropriate for many behavioral trials. The PEDRO and SIGN rating systems apply well to behavioral clinical trials (Bhogal, Teasell, Foley, & Speechley, 2005; www.sign.ac.uk/guidelines). It can be noted, though, that at our field's present stage of development, few high-quality RCTs exist. The scarcity of high-quality trials is such that, for many psychosocial interventions, implementing quality considerations beyond whether a study used randomization leaves too few remaining studies to synthesize quantitatively (cf., Spring et al., 2007).

The next step in systematic reviewing is design of a data extraction form and extraction of data on the primary outcomes. At this juncture, a decision usually needs to be made about whether to contact study authors to obtain data not available in their published reports. Data synthesis via meta-analysis comes next and requires decision-making about the handling of study heterogeneity. Nearly all systematic reviews of treatment reflect heterogeneity; a key question is whether it is so great as to preclude quantification of effects across studies.

An essential point is that not all systematic reviews synthesize data quantitatively via meta-analysis. Some systematic reviews explore reasons for heterogeneity on a purely qualitative basis. The optimal approach to handling heterogeneity is a very active area of investigation in systematic review science (Viechtbauer, 2007), as are questions of how

to adequately reflect data on harms (Chou & Helfand, 2005) or synthesize qualitative information (Dixon-Woods et al., 2007).

A semester-long course on systematic review is offered in most graduate training programs in public health, but such courses are rarely taught in psychology. Usually, meta-analysis is covered as part of statistics training. However, the remaining content—systematic reviewing, per se—is omitted, and warrants consideration for inclusion in psychology training.

Two online learning courses available free of charge at www.ebbp.org/training.html offer an introduction and background relevant to systematic reviews. The "Search for Evidence Module" provides an overview of how to acquire evidence. It is rich in information about useful search strategies and the extensive roster of databases relevant to psychologists. The "Systematic Review Module" covers topics such as judging the quality of a review, how and why high-quality reviews can reach different conclusions, and steps in conducting a systematic review. For those who want more in-depth coverage, the Cochrane Collaboration has recently published their comprehensive handbook for systematic reviewers (Higgins & Green, 2008).

PRACTICAL DECISION-MAKING: EVIDENCE USE

When psychologists integrate research evidence to engage in evidence-based decision-making with their clients, they act as consumers of the research evidence. Figure 7.1 might make it appear that integration of the three spheres involved in EBP could occur simultaneously, but that is not the case. Engaging in the EBP process entails performing a specific sequence of five steps (5 A's) that is known as the *evidence-based practice process*.

## The Evidence-based Practice Process

The five steps of the EBP process are depicted in Table 7.2. Also, an interactive learning module that walks learners through the five steps is freely accessible at www.ebbp.org/training.html. After assessing the problem, the clinician performs the following sequence: (1) *A*sk a question, (2) *A*cquire the evidence, (3) *A*ppraise the evidence, (4) *A*pply the evidence, and (5) *A*nalyze and *A*djust practice. Each step, described in greater detail below, is an integral component of the EBP process and represents a competency or skill to be mastered by the practitioner. Note that, rather than being considered a formal step in the EBP process, assessment is assumed to precede the onset of the process and to recur throughout it.

### Ask: Asking Questions

After assessing the client, the clinician poses important, practical questions in order to inform decisions about management or treatment of the presenting condition. Asking effective clinical questions involves formulating them in a manner that allows them to be readily answerable. Skill at framing "well-built" questions is an acquired competency (Council for Training in Evidence-Based Behavioral Practice, 2008).

**Table 7.2  Steps in the evidence-based practice process**

| | |
|---|---|
| Step 1 | Ask client-oriented, relevant, answerable questions about the health status and context of individuals or communities. |
| Step 2 | Acquire the best available evidence to answer the question. |
| Step 3 | Appraise the evidence critically for validity and applicability to the problem at hand. |
| Step 4 | Apply the evidence by engaging in collaborative health decision-making with the affected individual(s). Appropriate decision-making integrates the context, values, and preferences of the recipient of the health intervention, as well as consideration of available resources, including professional expertise. Implement the health practice. |
| Step 5 | Analyze the effects of the health practice and Adjust practice. Evaluate implications for future decision-making, disseminate the results, and identify new informational needs. |

From Satterfield, J.M., B. Spring, R.C. Brownson, E.J. Mullen, R.P. Newhouse, B.B. Walker, and E.P. Whitlock. (2009). Toward a Transdisciplinary Model of Evidence-Based Practice. *The Milbank Quarterly, 87*(2), 368–390. © Milbank Memorial Fund. Reprinted with permission.

Numerous kinds of uncertainty arise in clinical practice. The major types of uncertainty can be framed as questions about:

- *Assessment.* Questions about best ways of measuring, describing, or diagnosing a condition.
- *Treatment.* Questions that address interventions to prevent, contain, or improve biopsychosocial difficulties.
- *Etiology.* Questions about influences that cause or contribute to the onset of a health problem.
- *Prognosis.* Questions about the probable course and outcome of a health condition.
- *Harm.* Questions that concern potential adverse effects of interventions.
- *Cost-effectiveness.* Questions comparing the expenditures relative to outcomes yielded by two or more alternative clinical courses of action.

Because many questions will be generated for each client, prioritization of the most important ones needs to proceed in an efficient fashion. The chief criterion for prioritization usually concerns the impact of potential courses of action on the client's function or quality of life, or the perceived significance of the issue to the client (Council for Training in Evidence-Based Behavioral Practice, 2008).

Trainees learning to practice EBP are taught to differentiate two formats of question: background (general) and foreground (specific). Background questions aim to acquire general information about a condition, class of treatments, and the like. A well-formulated background question is comprised of two parts: (1) a question root (What, Who, How, etc.) including a verb, and (2) a disorder, treatment, or other health issue. Training in EBM devotes almost no attention to background questions. Such questions are too diffuse and yield too many citations to be used efficiently in the very brief time that most physicians have available for each patient. Clinical psychologists usually have longer to spend with each client. Additionally, in the authors' experience, many psychologists ask background questions in order to update their knowledge when first preparing to see a client. Subsequently, after having assessed the client in context, the practitioner proceeds to pose more focused and efficient foreground questions.

An example of a background question is: "What are effective treatments for binge eating disorder (BED)?" A clinical psychologist preparing to see a new client with BED might pose such a question in order to ensure that her knowledge of current best-treatment options is up to date. A subsequent foreground question might be, "In adults with BED: (P) Does interpersonal therapy (I) compared to cognitive-behavioral therapy (C) reduce the frequency of binge episodes (O). The better-focused foreground question will yield cites that specifically inform a decision about whether to proceed with interpersonal or cognitive-behavioral therapy, assuming the clinician is trained to provide both and both are acceptable to the client.

### Acquire: Acquisition of Evidence

Once a well-built question has been formulated, the next step is to acquire the evidence to answer it. This step requires the practitioner to translate the question into an efficient search plan. Help can be found at www.ebbp.org's online tutorial on searching, or via consultation from a librarian or other professional with expertise in information science. Navigating the sheer bulk of existing primary research can be daunting and time-consuming. Consequently, it is expected and advantageous that busy practitioners will turn first to the secondary, synthesized literature to answer their questions. Practice guidelines based on systematic reviews can be found at www.guidelines.gov or at the UK's National Institute of Clinical Excellence (www.nice.org.uk/Guidance/CG/Published). Useful search strategies for retrieving systematic reviews have also been published (Montori et al., 2005). The authors of a systematic review will already have compiled and critically appraised the quality of the primary research literature to answer many frequently asked questions. However, the clinician will still need to appraise the quality and relevance of the systematic review (Hunt & McKibbon, 1997).

#### APPRAISE: CRITICAL APPRAISAL OF QUALITY AND RELEVANCE

The next step in the EBP process is to critically appraise two aspects of the obtained evidence: its quality and its applicability to the client and circumstances at hand. In evaluating research on interventions, the key parameter to be appraised is internal validity: whether the research was designed and conducted in a manner that allows psychological or behavioral change to be attributed causally to the intervention rather than to extraneous influences. Applicability or relevance refers to the clinician's judgment about whether the research results can be generalized to the specific client, interventionist, and circumstances at hand.

The appraisal of relevance is challenging. Applying either overly stringent or overly lax criteria to judge applicability may have adverse consequences. If the body of evidence is seen as having no relevance to new groups and circumstances, then old, ineffective practices may continue to constitute usual care for many understudied and underserved populations. On the other hand, if interventions are assumed to be universally applicable, then the need to adapt treatment to attain client acceptance may be ignored. Given the limited body of research for psychosocial interventions, few treatments have been evaluated fully to determine their efficacy across demographic and cultural groups.

What should the clinician do when considering the prospect of delivering a well-established treatment to a patient from a demographic subgroup whose response to the intervention has not been fully characterized? One possibility is to search the primary research literature for evidence of treatment × subgroup interactions indicative of differential benefit or harm. Finding no evidence of treatment interaction, and assuming the client finds the treatment acceptable, the best available evidence suggests going ahead to implement the treatment. Of course, the necessary next step is to assess the results and adjust treatment accordingly. That "analyze and adjust" step, to be discussed shortly, is no less necessary when treating an individual from a well-studied population.

## Apply: Decision-making and Action

The "apply" step is at the heart of the EBP process. "Apply" is also the most complex and least described step in the EBP process model. During the apply phase, the clinician integrates knowledge from best available, relevant research with consideration of patient characteristics and resources to arrive at an action decision. After finding and appraising the evidence, the interventionist assesses the resources available to offer what research shows to be the intervention best supported by evidence. The considered resources include finances, linguistically appropriate materials, trained practitioners, client's ability to attend sessions, and other factors. The clinician also considers the likely acceptability and uptake of the best-supported treatment by the client. She evaluates the client's values and preferences by proactively engaging the individual in the process of collaborative decision-making. In some instances, other stake-holders (e.g., family members) may also be included in decision-making.

Resource appraisal usually requires the clinician to self-assess whether personal training and skills are adequate to implement best clinical practices. A challenge for EBP in clinical psychology is that, once an evidence-based intervention is identified, practitioners may not have the skills needed to implement the intervention. A decision then needs to be made, collaboratively, about whether to implement an alternative EBP in which the clinician is trained, or whether to refer (if a clinician skilled in the best practice is available and amenable).

For EBPs to be disseminated and implemented, practitioners need to know how to search for training resources. Materials are now readily available on many Internet sites. For example, the Substance Abuse and Mental Health Services Administration (SAMHSA) and its Center for Mental Health Services (CMHS) provides six Evidence-Based Practice Implementation Resource Kits to encourage the use of EBPs in mental health (Center for Mental Health Services, 2008).

## Analyze and Adjust: Evaluation, Dissemination, and Follow-up

A clinician engaging in evidence-based practice performs continuous practice-based quality improvement (Greiner & Knebel, 2003). During and after applying an evidence-based intervention, the practitioner analyzes outcomes and adjusts practice accordingly. The clinician engages the client and sometimes other stakeholders (e.g., family members) in the process of evaluation and quality improvement. Results are then used to refine local decision-making policies, generate new questions, and identify needed research.

The analyze and adjust step makes EBP an iterative process. Performing the step requires ongoing assessment, followed by realignment of treatment based upon local data from the patient. It is usually possible to perform such realignments within the scope of an EST without compromising the core features integral to the therapy. Analyze and adjust simply reminds the clinician of the need to monitor progress. However, in some instances the EST appraised as having highest quality and relevance may fail to help a particular client. To continue administering the same EST months after the client's condition has deteriorated would no longer constitute EBP. The clinician practicing EBP would analyze the deterioration and adjust course, probably by offering an alternative EST.

As noted earlier, the www.ebbp.org website offers an online experiential module to learn the EBP process. The EBP process module presents two alternative cases in which a practitioner addresses tobacco

use with a client. In one case, the client is an individual. In the other case, the client is a community. For those who prefer in-person training, conference workshops on EBP are offered at the Society of Behavioral Medicine, Association of Behavioral and Cognitive Therapy, and American Psychological Association. More extended courses on EBM are taught at several locales. Best known are the annual summer workshop on "How to Teach Evidence-Based Clinical Practice" taught at McMaster University in Canada, and courses by the Center on Evidence-Based Medicine at Oxford University in the UK.

## Conclusion

Engaging in EBP entails a process of lifelong learning as the evidence about best practices continues to evolve. Attaining mastery of skills needed to perform the EBP process is a process and not an event with an endpoint. The complexities of real-world practice, the proliferation of the research evidence base, the changing sociocultural and health-care contexts, and rapidly evolving health information technologies require ongoing engagement in the EBP process (McCourt, 2005; Michel, 2007).

Much is to be gained from engagement of psychology's research and practice communities in the EBP process. Ultimately, the goal of EBP is the provision of best-tested, most effective care to the public in a manner that reflects shared decision-making and mutual involvement in continuing to enrich the evidence base.

Psychology has a long tradition of excellence in research methodology. Indeed, clinical psychologists proposed a form of EBP based on empirically supported treatments before publication of the major initial papers on EBM. Inclusion of ESTs in the didactic curriculum of accredited clinical psychology programs has been a major achievement in the dissemination of evidence-based psychological treatments. Now, work is needed to increase further the availability of hands-on, supervised training in ESTs.

Also needed to participate fully in the EBP movement is increased education of psychologists in clinical trial and research synthesis methodologies. These methodologies are applied across health disciplines to evaluate the quality of support for preventive and treatment interventions. Provision of evidence from high-quality RCTs is likely to become increasingly important as a means by which policymakers will make coverage decisions. Conducting well-designed, carefully implemented, well-reported clinical trials, and synthesizing the evidence in systematic reviews are two ways that psychologists can contribute to EBP. Growth and dissemination of the evidence base for psychological treatments are vital in helping to ensure that the public continues to have access to the psychological treatments best supported by evidence. Clinical psychologists can contribute to EBP by acquiring the training and clinical skills needed to implement ESTs. Finally and critically important is the need for psychologists to master the steps of the EBP process in order to stay up-to-date as the evidence for best-supported psychological practices continues to evolve.

### Future Directions

• Gaps in the evidence base are a major impediment to EBP. How can psychology, as a discipline, prioritize which gaps warrant research attention most urgently in order to guide policy and practice?

• Psychological treatments represent a viable alternative or increment to medical–surgical treatments for many health problems, and psychological treatments are often preferred by patients. Inclusion of psychological treatments in comparative effectiveness trials would yield a sounder basis for coverage policies.

• Reasonable agreement has emerged about standards to appraise the quality of research evidence. Greater ambiguity surrounds the appraisal of whether research is relevant to the client and the context at hand. Can psychologists systematize a process for taking context into account when critically appraising whether evidence is relevant? For example, can decisional algorithms be derived and validated to judge the degree to which evidence derived from majority populations is applicable to cultural subgroups?

• How to implement the "apply" step of the EBP process remains undefined. Exactly how should the clinician integrate research evidence, client characteristics, and resources? How should the apply step be systematized? Will the optimal systematization take the form of practice guidelines, decisional algorithms, or something different?

• A vital component of EBP is the infrastructure needed to actively disseminate (i.e., "push") regularly updated syntheses of evidence to practicing clinicians. Will psychology as a discipline invest in creating infrastructure to support EBP? Will clinical psychology go it alone

on creating infrastructure for EBP, or will we partner with other psychological specialties and/or other health disciplines that offer psychosocial treatment?

# Training, Credentialing, and New Roles in Clinical Psychology: Emerging Trends

Catherine L. Grus

## Abstract

This chapter provides an overview of key developments in the education, training, and credentialing of clinical psychologists; new roles in the field; and intersecting issues across these domains. Emerging issues highlighted within education and training include the move toward the assessment of competence in trainees, accreditation developments, and the doctoral internship match imbalance. Changes in licensing laws, mobility, and the degree of coordination between education and training and credentialing systems are described. Expanded roles for clinical psychologist, such as in health-care settings and public health, are reviewed. Finally, emerging developments such workforce analyses conducted within and across health-care professions and the relationship of issues such to national policy initiatives that are and will impact the future of clinical psychology are presented.

**Key Words:** Competency, credentialing, health care, licensure, training, workforce

Clinical psychology is the largest subfield of psychology at the doctoral level. Over 49.8% of doctoral degrees awarded in 2006–2007 were in clinical psychology, to a total of 2,483 individuals (APA, 2008c). This is not new: Clinical psychology has long been the subfield in which more individuals earn a doctoral degree among all others in the field; in 2001, 50% of doctorates earned were in clinical psychology (APA, 2003). A majority of the doctorates awarded in psychology are to women, as many as 72% in 2005, whereas minorities account for 19% (APA, 2005). The number of individuals earning PsyD degrees has been steadily increasing and now number more than those earning PhD degrees. In 2005, 47% of doctorates in clinical psychology earned were a PhD degree, and 53% earned a PsyD degree (APA, 2008c; APA Center for Workforce Studies [CWS], 2007a).

Doctoral programs in clinical psychology accredited by the American Psychological Association also have grown in the past 10 years. As of the 2005–2006 academic year, there were 226 accredited

doctoral programs in clinical psychology, which comprised 61.7% of all accredited programs (APA Committee on Accreditation, 2006). This is an increase of 39 accredited programs over 10 years. These clinical psychology programs were responsible for the education and training of 77.4% of all students enrolled in professional psychology doctoral programs, an increase from 74.4% in 2001 (APA Committee on Accreditation, 2001). Correspondingly, student enrollment has also increased. In 2001, there were 16,528 students enrolled in APA-accredited doctoral programs in clinical psychology; as of 2006, this number jumped to 25,973—an increase of 57.1% (APA Committee on Accreditation, 2001; APA Committee on Accreditation, 2006). Thus, clinical psychology continues to be a thriving and growing area within the field.

This chapter describes emerging trends in clinical psychology, with a focus on education, training, credentialing, and new roles. An overview of key issues for the field will be reviewed across these domains. Education and training prepares the

individual for credentialing and practice, and serves as the cornerstone for entry into the profession. Education and training, in turn, should be guided by developments in the profession, including emerging roles, to ensure that students are properly prepared for the settings in which they will be working and the types of services they will provide. To that end, the linkages that are or should be occurring across these domains will be addressed with a focus on next steps for clinical psychology.

## Education and Training in Clinical Psychology

Education and training in clinical psychology is at the forefront of several exciting initiatives and issues, many of which are broadly facing professional psychology. A strong focus continues to be on mechanisms for enhancing quality in education and training, which will be discussed in light of developments in the areas of competency-based education and training, and accreditation. A particular challenge that will be discussed is the internship match imbalance—the number of students seeking internship training compared to the number of internship training positions available. Emerging issues in education and training include evidence-based practice (EBP) in education and training, the role of technology in education, links between undergraduate and graduate education in psychology, student debt load, and issues with respect to practicum training.

### *Competency Initiatives*

Perhaps one of the most significant developments in clinical psychology education and training—and, in fact, within professional psychology training more broadly—is the growing focus on measurement of student learning outcomes using the framework of competencies. The articulation of core competencies for professional psychologists dates back over two decades to a model developed by the National Council of Schools and Programs of Professional Psychology (NCSPP), which, in 1986, articulated six core competency areas (Peterson, Peterson, Abrams, & Stricker, 1997). However, in recent years, several major initiatives have taken place that have broadened the awareness and use of competency-based models of education and training in professional psychology. This series of events has been termed as a shift to a "culture of competence" (Roberts, Borden, Christiansen, & Lopez, 2005). Fundamentally, this shift represents a significant pedagogical change in which traditional models of education and training that were driven by curriculum and course objectives

are being replaced with a model in which the desired student learning outcomes, defined as competencies, shape the design of the learning experience (Nelson, 2006). The growing emphasis on competence as an outcome of education and training is not unique to professional psychology and, in fact, is occurring in other health-care disciplines, such as medicine, nursing, dentistry, and pharmacy (Medical School Objectives Writing Group, 1999; Spielman, Fulmer, Eisenberg, & Alfano, 2005; Watson, Stimpson, Topping, & Porock, 2002). Graduate medical education has moved to requiring all accredited programs to design their curriculum around, and measure student learning outcomes based on, six established core competencies (Accreditation Council for Graduate Medical Education, 2007).

The shift toward this culture of competence was accelerated and informed by psychology's 2002 Competencies Conference: Future Directions in Education and Credentialing. The outcome of that conference included agreement as to core competencies in professional psychology and a discussion of those methods of education and training leading to competence, including strategies for the assessment of competence (Kaslow, 2004; Kaslow et al., 2004). A further outcome of that conference was the conceptualization of a three-dimensional or "cube" model of competence development (Rodolfa, Bent, Eisman, Nelson, Rehm, & Ritchie, 2005). The model proposes that there are foundational competencies, which refer to the knowledge, skills, attitudes, and values that serve as the foundation for the functions a psychologist is expected to carry out, and these competencies are cross-cutting (e.g. reflective practice, ethics). There are also functional competencies that encompass the major functions that a psychologist is expected to carry out (e.g., assessment, intervention). The foundational and functional competencies intersect with one another and also vary by stage of professional development (e.g., doctoral level, internship, postdoctoral). This model has been widely embraced within professional psychology education and training, and has served as the guiding framework for two subsequent initiatives that have also had a significant impact on education and training: the Competency Benchmarks and the Competency Assessment Toolkit for Professional Psychology (Fouad et al., 2009; Kaslow et al., 2009).

The Competency Benchmarks is a document developed by a 32-member work group that met for 2 days in 2006; following this meeting, detailed revisions and enhancements were made during

following 2 years (Fouad, et al., 2009). The document outlines 15 core foundational (professionalism, reflective practice, scientific knowledge and methods, relationships, individual and cultural diversity, ethical and legal standards and policy, interdisciplinary systems) and functional (assessment, intervention, consultation, research and evaluation, supervision, teaching, administration, and advocacy) competencies. Each of the core competencies is defined and then their essential components are further elaborated in detail. As an example, one of the core functional competencies is consultation, defined as the ability to provide expert guidance or professional assistance in response to a client's needs or goals. Consultation is comprised of four subdomains, for which essential components are articulated, specific to each stage of education and training: role of consultation, addressing the referral question, communication of findings, and application of methods (of consultation). For example, at the readiness-to-enter-practice level, the essential component of the role of the consultant is: "Determines situations that require different role functions and shift roles accordingly." Each essential component, in turn, has a series of benchmarks or operational definitions of the essential component, termed *behavioral anchors*. These behavioral anchors address the question, "What would this essential component look like if it were observed?" Essential components and their behavioral anchors are presented at three levels of the professional development sequence—readiness for practicum, readiness for internship, and readiness for entry to practice—and are graduated to reflect the development of competence across the sequence of education and training. Following the readiness-to-enter-practice example given previously, the behavioral anchors are: (1) recognizes situations in which consultation is appropriate and (2) demonstrates capability to shift functions and behavior to meet referral needs.

Defining and operationalizing the core competencies, across the developmental sequence of education and training, was a significant step in this shift to the culture of competence. However, also necessary to the assessment of competence is the establishment of approaches to best practices. The Competency Assessment Toolkit for Professional Psychology (Kaslow, et al., 2009) will address this need by developing a toolkit for the assessment of competence. The Toolkit was informed by similar efforts in general medicine (Accreditation Council for Graduate Medical Education and American Board of Medical Specialties; 2000). Further, the

work on the Toolkit was guided by efforts of the APA Board of Educational Affairs (BEA) Task Force on Assessment of Competence in Professional Psychology, which was convened in 2004 (Kaslow et al., 2006). The report of the task force and subsequent publications provide an overview of the competencies movement within professional psychology (Rubin et al., 2007), assessment models from other health professions (Leigh et al., 2007), challenges in the assessment of competence (Lichtenberg et al., 2007), and guiding principles for the assessment of competence (Kaslow et al., 2007).

Components of the toolkit include a series of fact sheets that describe 15 different assessment methods (e.g., rating forms, portfolios, standardized patients, etc.) of relevance to psychology education and training. Each fact sheet describes the method, its application to the assessment of competence, its implementation, and notes the available psychometric data, and it describes the strengths and challenges of the method. Further components of the toolkit include a grid that provides recommendations as to which assessment methods are best suited to assess specific core competences and their associated essential components, a glossary of terms, suggested references for further information, and a historical review of the competency movement in psychology.

Applying models of education and training that are based on the assessment of competence will pose several challenges for the field. New assessment tools need to be developed, and existing measures must be adapted for use in the assessment of competence. The role of assessment in education and training will require broadening to include regular use of formative evaluation (used to guide students toward ongoing development), as well as the use of summative evaluation to ascertain readiness to move to the next level in the sequence of training. Another challenge is posed by the fact that competence is developmental—expectations differ over time, and may not be demonstrated consistently across situations; two factors that must be addressed in both the design and interpretation of assessment results. Further, those charged with conducting the assessment of competence must be trained in the appropriate use of such methods, as well as how to optimally give student feedback in ways that meaningfully shape the education and training process.

Despite these challenges, given the focused effort that has been devoted to defining and assessing competence in professional psychology (as evidenced by the number of large-scale national initiatives), it

seems unlikely that this will be a short-lived trend. The adoption of similar models by other health-care disciplines, as well as a focus at the national level on the importance of measuring student learning outcomes, also supports the continued role that competency-based education and training will play in psychology. Specialty-specific models have been developed, building on the cube model, for both geropsychology and clinical health psychology (Borrayo, 2006; France et al., 2008). Further, as will be discussed in later sections of this chapter, the developments within education and training on defining and measuring competence have relevance to efforts within credentialing, which has as its fundamental premise the assessment and awarding of a credential to those who demonstrate competence.

### Developments in Accreditation of Education and Training Programs in Clinical Psychology

The APA Commission on Accreditation serves as the oversight body charged with evaluating and recognizing quality education and training programs in professional psychology—including clinical psychology—and for doctoral, internship, and postdoctoral programs. Although the Commission engages in ongoing discussion and takes action to enhance quality through its policies and procedures, three key events will be highlighted: the 1996 revisions to the Guidelines and Principles for Accreditation, the accreditation of programs in "developed practice areas," and the recent transition of the Committee on Accreditation to the Commission on Accreditation.

In 1996, revisions to the Guidelines and Principles for Accreditation of Programs in Professional Psychology were approved. One of the key changes was to move away from documenting the curriculum of the training program to an emphasis on outcomes assessment (Nelson, 2007). Specifically, programs are now required to declare a program model or philosophy of training and to demonstrate relevant outcomes, including the acquisition of competence across the broad and general domains of professional psychology. Although a number of training models have been broadly promulgated within professional psychology, clinical psychology programs have tended to identify with four models: Scientist-Practitioner, Practitioner-Scholar, Clinical Scientist, and Local Clinical Scholar.

The Scientist-Practitioner model is the model employed by the majority of doctoral programs in clinical psychology (Belar & Perry, 1992) and traces its origins to the Boulder Conference held in 1949, which was prompted by a need to better articulate what was, at that time, an emerging model of training in clinical psychology in which doctoral-level psychologists were beginning to be trained as service providers (Raimy, 1950). The Scientist-Practitioner model described the balance of preparing students for careers as both scientists and providers of services, a stark contrast from psychology's earlier history of focusing solely on research. In 1990, a national conference was held for the purpose of articulating the key features of the Scientist-Practitioner model, and delegates to that conference reaffirmed the importance of this model in the education and training of psychologists (Belar & Perry, 1992). The model, as articulated in the conference policy statement, involves the development of integrated skills within science and practice and is responsive to the changing knowledge and practice base within the field (Belar & Perry, 1992).

The Practitioner-Scholar model emerged as the outcome of another national training conference held in Vail, in 1973 (Korman, 1976). The impetus for the conference was dissatisfaction by some with training under the Scientist-Practitioner model, particularly in the area of how social issues were addressed (Belar, 1992). The Practitioner-Scholar model emphasizes the preparation for psychological practice that is informed by science. The Vail conference made a specific endorsement of the doctorate of psychology, and the participants recommended that the PsyD degree be awarded upon completion of the doctoral degree in a professional psychology program, given the training emphasis in these programs on the direct delivery of services and the evaluation of the efficacy of such (Korman, 1976).

The Local Clinical Scientist model notes that the clinician functions as a scientist, but in the local setting in which services are provided, thus the setting serves as a "metaphorical scientific laboratory" for the clinician (Stricker & Trierweiler, 2006). According to the Local Clinical Scientist model, data are gathered and combined with observations of the setting and the experience of the practitioner. Critical, scientific thinking is encouraged, as well as the application of scientific knowledge to clinical issues. Further, the model notes that the clinician is an active scientist and not acting as an applied scientist (Stricker & Trierweiler, 2006).

Clinical psychology also developed an education and training model specific to clinical psychology, known as the Clinical Scientist model, which also grew out of discontent with the Scientist-Practitioner

model (McFall, 1991). A specific criticism raised against the Scientist-Practitioner model was that it does not promote the unification of science and practice; further, the goal of doctoral education is not to train individuals to work in specific settings, but to train scientists. McFall (1991) raised concern that the focus of education and training had shifted to mastering techniques and demonstrating that one had acquired knowledge. What was missing was critical thinking, mastery of scientific principles, and the solution of new problems by the independent application of scientific knowledge, principles, and methods. The Clinical Scientist model holds that the overarching goal of doctoral training is to produce competent clinical scientists who will practice as scientists.

Each of these models has a distinct origin and focus, and they are prominent constructs in education and training programs in clinical psychology. The decision to require education and training programs to identify a model of training and then to allow the model to be identified by the program for accreditation purposes has been criticized by some. It has been argued that such proliferation has allowed for a (continued) diffusion of the core identity of professional psychology (Benjamin, 2001). Nonetheless, the continued recognition of these models and their importance to the broadening definition of the field is attested to by their codification in the APA's procedures for accreditation of programs in professional psychology.

A second major policy development in accreditation was the establishment of criteria and a mechanism to accredit doctoral and internship programs in developed practice areas, which went into effect in 2007. Historically, accreditation was limited to programs in the broad specialty areas of clinical, counseling, or school psychology, or a combination of these. A developed practice area must have been recognized by an appropriate national organization, have a body of knowledge providing empirical support for the practice area, have a national training council that is recognized and active, develop and disseminate education and training guidelines, exist within established education and training programs, and have practitioners in the practice area who are geographically dispersed (APA Commission on Accreditation, 2008). Although no developed practice areas have as yet been recognized, this offers an expansion in the scope of programs eligible for accreditation. Such areas as clinical child psychology, for example, have long argued their distinctiveness (Roberts, 2006).

Finally, in 2008, the Committee on Accreditation became the Commission on Accreditation, increasing from 21 members to 32 (APA, 2008c). This change was approved by the APA Council of Representatives in 2006, based on recommended changes proposed at what is known as the "Snowbird Summit," which was convened in 2005, and based upon several years of due-diligence review of the accreditation structure. The increased number of members allows for a commission that more closely mirrors the representation of the diversity of professional psychology in terms of specialty training areas (e.g., clinical, counseling, school, NCSPP, the Academy of Psychological Clinical Science, the Council of Specialties), as well as in terms of levels of training (doctoral, internship, and postdoctoral). Further, in the future, accreditation of programs will be conducted by panels consisting of several members from a specific doctoral training model (as described earlier), with the intent of enhancing the quality of the review process by having specific expertise applied to the review of programs using a specific model.

### Doctoral Internship Match

The doctoral internship required for completion of the doctoral degree in clinical psychology has been a focus of attention within clinical psychology and more broadly across all programs preparing the next generation of health-service providers. Specifically, recent years have seen large and increasing numbers of students failing to obtain an internship through the internship match process sponsored by the Association of Psychology Postdoctoral and Internship Centers (APPIC). In that process, students rank-order their preference for training sites, and training sites rank-order their preference for students. At a given date, the lists are "matched" and students are thereby chosen for their internship placement. Although the number of internship positions increased by 174 to a total of 3,058 in the 2008 APPIC internship match, this growth was insufficient to meet the demands of the 3,492 students seeking an internship, resulting in an overall match rate of 79% (APPIC, 2008). Although this figure is slightly better than the 75% match rate in 2007, it represents 743 and 842 individuals who went unmatched in the 2008 and 2007 APPIC internship matches, respectively. The number of students who did not obtain an internship in the match in 2007 was the largest in any year since the inception of the computerized match in 1999. Survey data collected by APPIC of students who

participated in the 2007 match indicates that students from clinical psychology programs matched at rates comparable to other specialty areas (79% vs. 78% for counseling, 84% for school, 80% for combined) (APPIC, 2007).

Although the numbers of students who do not obtain an internship through the APPIC match process has increased to record levels, there is a long history of imbalance in the match (Kaslow & Keilin, 2006). National attention was focused on the internship match imbalance at a 1997 meeting cosponsored by the APA and APPIC titled, "Supply and Demand: Training and Employment Opportunities in Professional Psychology" (Pederson, DePiano, Kaslow, Klepac, Hargrove, & Vasquez, 1997). This working conference focused on the supply-and-demand issues in professional psychology, with the goal of developing action steps that would better prepare psychology students at all levels of training for the changing employment market. Several resolutions were passed by the participants, such as a request for greater attention to systematic data collection, gathering more information about students seeking internship, and a recommendation that APA and APPIC should work together to develop and publicize data sets that are national, regional, and program-specific. As two of the national organizations most directly concerned with the internship match imbalance, APPIC and APA have both engaged in additional and ongoing efforts related to the internship match imbalance. The APPIC has provided mentorship to and consultation with new and developing internship programs and educational outreach to students and training faculty. Both groups have been involved in efforts to provide data about match outcomes to the public to both inform and assure transparency in the process. The APPIC has been collecting and disseminating comprehensive statistical data on match outcomes on its website (Baker, McCutcheon, & Keilin, 2007). The APA now collects and publishes data about specific program match outcomes in its publication *Graduate Study in Psychology*, which is also available in an online version. The creation, in 2006, of the APA Center for Workforce Studies, described in detail later in this chapter, will provide a data-based perspective of the field of psychology that is necessary to understand possible pathways toward improvement (Rozensky, Grus, Belar, Nelson, & Kohout, 2007). Further, the APA engages in advocacy initiatives to raise awareness about the critical need for funding for psychology education and training. For example, the Graduate Psychology

Education Program (GPE), which was established in 2002, was funded by the U.S. Congress at $1.8 million in 2007 and 2008, and hopes to be funded at $4 million in 2009 (APA, 2008a). The GPE grants provide support to education and training programs whose students provide services to underserved populations in interdisciplinary settings.

Despite these and other efforts to address the APPIC internship match imbalance, it has persisted. In recognition of this, in 2007, a special issue of the *Journal of Training and Education in Professional Psychology* was published, in which articles addressing this issue were written by the various doctoral training councils, APPIC, APA, and the American Psychological Association of Graduate Students (APAGS). Each article offered observations on the nature of the internship match imbalance and proposed efforts to address the imbalance. Collins, Callahan, and Klonoff (2007), providing a perspective from the Scientist-Practitioner model, proposed a "Stairway to Competency" model, and urged the focus of the field to shift away from a focus on the attainment of an internship and to those methods by which competence is developed in students and to the role that internship training and the program–internship match play in the development of competencies. Entry-level competence, which is at the top of the stairway model, is built upon trainee characteristics, the doctoral program, and the internship year. Hutchings, Mangione, Dobbins, and Wechsler (2007), representing the perspective of NSCPP note three factors contributing to the internship match imbalance: decreased financial support for internship training, a relative lack of connectivity between doctoral programs and internships, and that internships tend to be housed in traditional settings and have not yet moved into the breadth of practice settings in which psychologists are employed. They advocate for expanding internship sites and positions as one of the more viable pathways to improve the internship match imbalance. Other suggestions include the need for ongoing advocacy initiatives aimed at securing funding for internship training, looking at innovative ways to support training, and for examining the sequence and structure of doctoral training.

Concerns have been raised about the impact of the internship match imbalance on the quality of internship training that students receive. These include students failing to develop the necessary competencies for entry-level to practice (Collins, Callahan, & Klonoff, 2007) and a possible push to lower standards for internship training or eliminate

the doctoral internship altogether (Baker, McCutcheon, & Keilin, 2007; Keilin, Baker, McCutcheon, & Peranson, 2007). This is a significant issue for clinical psychology (and all of professional psychology), and will require ongoing attention and efforts directed toward pathways that will address the internship match imbalance.

## Emerging Trends in Education and Training

Several emerging trends relevant to education and training in clinical psychology will be mentioned. These include training in EBP, the role of technology in education, linkages between undergraduate and graduate education and training, the balance between preparing students for practice and for the production of scientific knowledge, practicum training, and debt loads for those earning doctorates in psychology.

### TRAINING IN EVIDENCE-BASED PRACTICE

The scientific foundations of practice in psychology are a required component of the doctoral curriculum for programs accredited by the APA (Belar, 2003). All four training models that are typically employed by clinical psychology education and training programs emphasize the role of science as it relates to practice (Hunsely, 2007). So, although not a new focus for education and training, the use of EBP has become a large-scale conversation across health professions in recent years, including policy statements advocating for the use of EBP issued by both psychology and medicine (APA, 2005; Institute of Medicine [IOM], 2001, p. 147). Evidence-based practice, as defined by APA policy is, "the integration of the best available research with clinical expertise in the context of patient characteristics, culture, and preferences" (APA, 2005). Medicine adopted a similar statement in 2000 (IOM, 2001). Some of the challenges for education and training programs seeking to provide training in EBP include finding a balance between instruction in the science behind a method without neglecting attention to the patient as an individual (Belar, 2003). It is also necessary to train students in self-assessment, such that self-directed study can occur and prepare students to engage in lifelong learning (Belar, 2003; Hunsely, 2007). Further evidence must be gathered about best teaching methods to train in EBP, and supervisors need to model the use of EBP to their trainees (Belar, 2003). Challenges identified by training directors include the need to clarify if the intent of training is to teach a specific protocol

versus training in the principles of EBP, lack of time, lack of trained supervisors, lack of an evidence-base for all clinical issues that students will be expected to confront in practice, and opposition to the approach, as it can be perceived to limit one's autonomy as a provider (Woody, Weisz, & McClean, 2005). These challenges must be addressed by education and training programs in clinical psychology, both now and in the future.

### TECHNOLOGY IN EDUCATION

The role of technology in education and training has become greater, offering both challenges and opportunities for clinical psychology. Technology has become infused in education and training across all levels and settings, and includes classroom-based tools and technology to capture student performance for evaluation purposes, as well as its application in supervision and distance learning programs. The delivery of quality education and training using distance learning methods and the use of technology to evaluate and supervise clinical training are tools that are being used in education and training at the doctoral level in psychology.

Distance education is increasingly popular across other health professions and in education in general. Distance education programs are diverse, and can vary from students gathering at a satellite location to those programs that are primarily Internet-based with little in-person, face-to-face interaction (Murphy, Levant, Hall, & Glueckauf, 2007). For psychology, the application of traditional models for quality assurance of education and training programs to distance education programs poses a challenge that has yet to be resolved (Murphy, Levant, Hall, & Glueckauf, 2007). Specific areas that will require continued focus include the roles of mentorship, pedagogy, and residency in distance education (Nelson et al., 2008, pp. 30-31). Distance education may offer opportunities to enhance education and training through improved communication with students on internship, to present courses with low enrollment at one site to students across many sites, and to broaden exposure to cultural diversity (Murphy et al., 2007). Technology, in the form of *telehealth*, offers additional opportunities for education and training in psychology, particularly in rural settings. Telehealth can reduce barriers to face-to-face supervision secondary to distance between practice settings (Wood, Miller, & Hargrove, 2005). Further, it is likely that computer technology will serve an increasing role in the assessment of competence for professional practice in

both education and training, and at the level of licensure (Nelson, 2007).

## LINK TO UNDERGRADUATE CURRICULUM

Another future challenge for clinical psychology is fostering better linkages across levels of education and training. Although efforts, such as the communication guidelines developed by the Council of Chairs of Training Councils (CCTC, 2007), to address the perceived lack of continuity between doctoral and internship programs, limited systematic attention has been given to the connection between undergraduate and doctoral education in psychology. Interestingly, attention to issues of quality in education and training advanced through the assessment of competence now pervades discussion in both groups, although, to date, these discussions have occurred independently. Guidelines developed for the undergraduate psychology major outline ten goals and learning objectives applicable across educational settings (APA, 2007). The guidelines articulate the knowledge, skills, and values to be acquired with respect to the science and application of psychology, and with respect to a liberal arts education, that are then further developed in psychology. Future directions would include mapping the undergraduate guidelines and the benchmark documents onto each other to look for overlap, continuity, and opportunities to enhance that continuity.

## BALANCE BETWEEN PREPARING STUDENTS FOR PRACTICE AND FOR THE PRODUCTION OF SCIENTIFIC KNOWLEDGE

As noted in the discussion of the common education and training models employed by clinical psychology doctoral programs, all emphasize the role of a background in science and practice as necessary for those training to practice clinical psychology. Although psychology has its historical roots as a science-based profession, growing numbers of individuals are choosing to focus their careers on the practice of psychology and less on the production of new scientific knowledge, as exemplified by the growing popularity of doctoral programs leading to the PsyD. Further, this balance may be influenced by students who are seeking to enhance their "competitiveness" in the APPIC internship match through ever-increasing hours of training (Kaslow & Keilin, 2006; Miville, Adams, & Juntunen (2007).

Merlo, Collins, and Bernstein (2008) offer data that suggest that clinical psychology education and training programs have been able to maintain a balance between training to produce scientific knowledge and practice training. In a sample of clinical psychology programs that emphasized science and practice training, students using a 5-point scale to report the rating of the mix of practice and science training rated their programs at 3.53 (5 = primarily research focused). Students reported spending an average of 37% of their time in research training activities, as compared to 29% in clinical training activities. Overall, students, on average, reported optimal levels of training. In contrast, in a survey of counseling psychology doctoral programs, Miville, Adams, and Juntunen (2007) reported that 36% of their sample reported decreased emphasis on research training as result of increased focus on helping students with the internship match process.

Although the current internship match imbalance may be highlighting the balance of training for practice and for the production of scientific knowledge in clinical psychology, these concerns were raised early on by participants in the Vail Conference (Korman, 1976), which recommended that a clear delineation should be set between the PsyD and PhD degrees in psychology. The PhD degree was appropriate for those programs whose focus was on education and training to develop new knowledge in psychology. The PsyD degree should be awarded to those programs that prepare students for the practice of psychology. More recently, L.W. Craighead and W.E. Craighead (2006) proposed that clinical psychology doctoral programs should offer a joint PhD and PsyD degree if their intent is to train researchers and clinicians who would go on to seek licensure. In contrast, the PhD degree should be awarded solely as a research degree. The field will likely continue to struggle with the balance between preparation for practice and for the production of scientific knowledge in the education and training of clinical psychologists. As Benjamin (2001) noted, the field cannot answer the question, "what is a psychologist," in that we have neither defined the field nor identified a core curriculum.

## PSYCHOLOGY PRACTICUM TRAINING

Another issue in professional psychology education and training that has been emerging more recently relates to the quality, quantity, and details of psychology practicum training. Increases in the numbers of practicum training hours are occurring, with students accruing more hours in hopes that this will enhance their standing as an intern applicant (Kaslow & Keilin, 2006; Ko & Rodolfa, 2005; Rodolfa, Ko, & Peterson, 2004). Ko and Rodolfa (2005) reported that a majority of academic, internship, and

postdoctoral training directors felt that there should be a minimum required number of practicum hours prior to internship. However, academic training directors reported a significantly lower number of minimum hours than the other two groups. Respectively, the mean number of hours reported as optimal prior to internship were 1,094, 1,255, and 1,233 for academic, internship, and postdoctoral program directors, respectively. These are all well below the average number of hours that students are reporting—with an average of 1,941 reported for 1989–1999; 2,199 for 2002; and 1,896 in 2003 (Ko & Rodolfa, 2005).

In an effort to address the issue of quality practicum training as assessed through attending to the competencies students acquire, Hatcher and Lassiter (2007) report on the development of the Practicum Competencies Outline, which was prepared by a work group formed by the Association of Directors of Psychology Training Clinics (ADPTC) whose members are directly involved in psychology training clinics offering practicum training. The efforts of this work group were later folded into efforts of a work group formed by CCTC, which approved a final document in 2005 (Hatcher & Lassiter, 2007). The intent of this project was to approach the issue of practicum competencies from a developmental and training-focused perspective. Specific goals were (a) to define the knowledge, skills, and attitudes needed prior to beginning practicum training; (b) articulate the domains of competency in professional psychology; and (c) define the level of competence that would reasonably be expected to occur at the completion of practicum training. The Practicum Competencies Outline provides a structure for the assessment of competence in students as they prepare to enter practicum training and as move through their practicum training experiences, thus offering an alternative to existing models of education and training that have focused on obtaining hours of training in absence of attention to the outcome of the training, as measured in the assessment of competence (Kaslow & Keilin, 2006).

DEBT LOAD

With more than 70% of doctoral degree recipients in clinical psychology reporting that it takes 5–6 years to complete their degree, financing graduate education is a significant issue (APA, 2008b). Loans, student earnings, and family financial support were reported to make up 69.4% of support for students enrolled in clinical psychology doctoral programs. In contrast, 50.8% of those earning doctorates in

research or other subfields of psychology reported research/teaching assistantships as their primary source of financial support (as contrasted to 22.9% of clinical psychology students) (APA CWS, 2007b). Students in clinical psychology doctoral programs are more likely to incur debt than are their counterparts in research and other subfields of psychology (79% vs. 52%), with an average debt of over $82,000 at the time of receipt of their doctorate (APA CWS, 2007b).

The setting in which students obtain their doctorate appears to be a primary factor in regard to the amount of debt incurred. Rapoport, Kohout, and Wicherski (2000) note that, during the period from 1993 to 1996, PhD degree recipients from professional schools of psychology (as compared to traditional universities) were more likely (41% vs. 15%) to have debt in excess of $30,000. As noted previously, over 50% of clinical psychology doctorates are PsyD degrees, and a majority of PsyD programs are located within professional schools of psychology. When compared to other science and engineering PhD degree recipients, the debt incurred by psychology doctoral students exceeds that of all other fields, with an excess of $30,000 of debt reported by 19% of all doctoral recipients in psychology. The next closest field was social science at 8% (Rapoport, Kohout, & Wicherski, 2000).

The implications of debt load on the future of clinical psychology remain unclear, although enrollments are up and more programs continue to become accredited by the APA, thus suggesting that it remains a popular career option. The interplay of the debt load issue and the internship imbalance remain contemporary problems in need of discipline-wide attention.

## Credentialing

Just as with education and training, credentialing in clinical psychology is also confronting several emerging and ongoing issues. This section addresses issues such as changes to licensing laws specific to when license eligibility occurs, mobility for psychologists, specialty board certification, and the Examination for Professional Practice in Psychology (EPPP). Emerging opportunities in credentialing will be discussed, focusing on the intersection and linkages between education, training, and credentialing in psychology.

### *Changes in Psychology Licensing Laws*

In some jurisdictions, 2007 and 2008 ushered in significant changes to psychology licensing laws,

relative to the point in the training sequence at which one is eligible to seek licensure. These changes are secondary to a 2006 policy statement approved by the APA that addresses when in the sequence of education and training an individual might be considered eligible to become licensed:

> The American Psychological Association recommends that for admission to licensure applicants demonstrate that they have completed a sequential, organized, supervised professional experience equivalent to 2 years of full-time training that can be completed prior or subsequent to the granting of the doctoral degree. For applicants prepared for practice in the health services domain of psychology, one of those 2 years of supervised professional experience shall be a pre-doctoral internship.
> (*APA*, 2006)

This policy is a significant departure from previous guidelines, which stated that a period of post-doctoral training was needed prior to seeking licensure for independent practice, as reflected in documents such as the APA Model Act for Licensure (Office of Professional Affairs APA, 1987) and the ASPPB Model Act for Licensure of Psychologists (Rodolfa, Ko, & Peterson, 2004). In 2004, a majority of states (92%) required postdoctoral experience prior to being eligible for licensure (Rodolfa, Ko & Peterson, 2004). The policy had its origins in the APA Commission on Education and Training Leading to Licensure in Psychology that was convened in 2000, in response to the difficulties experienced by students seeking postdoctoral supervised hours for licensure (Olvey, Hogg, & Counts, 2002). The Commission drafted a report maintaining that 2 years of experience should be required for licensure, but it recommended flexibility in the timing and sequence of 2 two years. One of those years should be the doctoral internship, the second could either be completed as practicum or in a postdoctoral fellowship. After the report was received, it was decided that no action would be taken for a period of 5 years from the meeting of the Commission. In 2005, the APA Board of Directors Work Group met to review progress within the field relevant to the Recommendations of the Commission as a context for considering any change to APA policy. The report of the Work Group led to the policy statement that was passed in 2006. Although there have been misperceptions that the intent of the policy is to eliminate postdoctoral training, the policy does make an explicit statement on the continued importance of postdoctoral education in training.

In the United States and Canada, each jurisdiction has its own psychology licensing laws, thus each will have to decide whether to seek changes within its jurisdiction. So far, the policy statement has led to changes in state licensing laws in Washington state and Utah, with a bill proposing changes pending in Ohio. Several other states are discussing the possibility of making changes. One consequence of these changes in licensing laws is that changes are being made in the education and training requirements for licensure, most evident with respect to increased specificity about the nature of practicum experiences that are acceptable to count toward licensure. As a result, the Association of State and Provincial Psychology Licensing Boards (ASPPB, 2008b) convened a Practicum Task Force that met in 2007 to craft model statutory language that could be used by state licensing boards concerning the practicum training experiences used to qualify for licensure. The task force was convened as several jurisdictions had or were seeking to make changes consistent with the 2006 APA policy statement. By drafting model language, the ASPPB sought to encourage the use of consistent standards across jurisdictions. A final draft of the model regulations is expected to be approved (ASPPB, 2008b). Such changes raise another credentialing issue of significance for professional psychology, including clinical psychologists: the issue of mobility for those seeking licensure in other jurisdictions at a later point in their career.

### Licensure and Mobility

With each jurisdiction in the United States and Canada having different requirements for licensure, and as psychologists broaden their practice settings to work in multiple jurisdictions, mobility for psychologists is increasingly discussed (Hall & Boucher, 2003). Although attempts at automatic reciprocity have not been successful, three vehicles exist that facilitate mobility for licensed psychologists seeking licensure in a different jurisdiction: (1) "banking" one's credentials with the National Register of Health Service Providers in Psychology (National Register), (2) the Certificate of Professional Qualifications in Psychology (CPQ) available through the ASPPB, and (3) specialty board certification by the American Board of Professional Psychology (ABPP). Each of these mechanisms offers endorsement of one's credentials, which facilitates the licensure process, but does not supplant the state- or jurisdiction-based process (Hall & Boucher, 2003).

The National Register is a credentialing organization that verifies that health-service providers have obtained a doctoral degree in psychology, completed supervised experience, and possess an active, unrestricted license to practice at the independent level with no disciplinary sanctions (Hall & Boucher, 2003). The CPQ also includes verification of one's credentials, certifying that one has meet the criteria for license eligibility, but has the additional requirement of licensure for at least 5 years (DeMers & Jonason, 2006). Agreements to accept the CPQ have been reached in 39 jurisdictions, with eight others in process, and eight that "recognize" the CPQ (ASPPB, 2008a). The ASPPB also maintains a credentials bank. Being able to bank one's credentials is an important concept for students. Both the programs by the National Register and ASPPB offer students the opportunity to submit documentation of the components required for licensure as they are completed and, by banking one's credentials with one of these organizations, they are more readily available if needed later in one's career (DeMers & Jonason, 2006; Hall & Boucher, 2003). Specialty board certification by the ABPP, which will be described in detail in a later section, requires the applicant to submit documentation of his or her education and training qualifications as part of the specialty certification process. Many jurisdictions will accept the ABPP as verification that the education and training requirements for licensure have been met (Hall & Boucher, 2003). There are costs involved for the student or licensed professional who chooses to use these services to maintain documentation of their credentials.

In Canada, the Mutual Recognition Agreement (MRA) has been successful in facilitating mobility for psychologists who seek licensure in a province or territory other than the one in which they are currently licensed. Further, the MRA is a model of how the assessment of competence can be used in the credentialing process for psychology (Nelson, 2007). Development of the MRA was triggered by a 1994 agreement by federal, provincial, and territorial governments to reduce barriers to mobility for workers, goods, services, and capital between the territories and provinces of Canada. The MRA, which was signed in 2001, defines parameters that allow for a psychologist who is licensed at the independent level to have his or her qualifications in one jurisdiction recognized in another. A key feature of the MRA is that it is a competency-based agreement, with applicants required to demonstrate competency

in five core areas using a variety of sources and methods (Gauthier, 2002). These competency areas are interpersonal relationships, assessment and diagnosis, intervention and consultation, research, and ethics and standards.

A future challenge in credentialing is the issue of global mobility, as more psychologists extend their practice outside the United States and Canada, consistent with the increasing globalization of society. Opportunities exist for psychologists to provide services either physically in other countries or virtually through the use of technology (Hall & Lunt, 2005). As a result, there is a growing desire for a global mobility process that is both easy and efficient. For several reasons (including the varying educational requirements to become a psychologist across different countries) efforts are being directed toward advocating for mechanisms by which endorsements of credentials can be recognized across countries, as opposed to attempting the daunting feat of trying to reach consistency among the credentials awarded (Hall & Lunt, 2005). To date, efforts have not moved beyond the level of developing the framework by which international mobility for psychologists might be facilitated. Developing standards remains to be done, and presents a future challenge for the field (Hall & Lunt, 2005).

## Advanced Credentialing and Specialization

Licensure for a psychologist is an entry-level credential and generic in scope (i.e., one is licensed as a psychologist and not, for example, as a clinical psychologist) in the majority of jurisdictions (Dattilio, 2002). Advanced credentialing, in the form of board certification, is a method by which the public and other professionals can be assured that a psychologist has demonstrated the skills and qualifications required to practice in a specialty area (Dattilio, 2002). Board certification, after initial licensure, is the model routinely employed in medicine for physicians. The oldest and most recognized entity offering specialty board certification to psychologists is the ABPP, which has been in existence since 1947 and recognizes and certifies 13 specialty areas (Packard & Simon, 2006) including cognitive and behavioral psychology, clinical psychology, clinical child and adolescent psychology, clinical health psychology, clinical neuropsychology, counseling psychology, family psychology, forensic psychology, group psychology, psychoanalysis in psychology, rehabilitation psychology, school psychology, and

organizational and business consulting psychology. Board certification is a voluntary process, offering the psychologist the opportunity to document specialized expertise in a specific domain. Board certification by ABPP requires all applicants to have earned a doctoral degree from an APA or Canadian Psychological Association accredited program or a program designated by the National Register, and to be licensed at the independent-practice level. Each of the specialty boards in turn has a board-specific examination that typically includes submission of representative work samples and an oral examination.

Despite the potential advantages for the field, as well as for the individual provider, offered by obtaining board certification, the numbers of psychologists certified by the ABPP is relatively low compared to the overall number of licensed psychologists. Estimates suggest that less than 3.5% of licensed psychologists or just over 3,300 have obtained board certification through the ABPP (Dattilio, 2002). Possible reasons include the costs associated with seeking board certification, time, misperception about the pass rates, and questions about the value added by board certification. However, in some employment settings, such as hospitals, board certification is required or expected (as it is within medicine) and in others, such as the Veteran's Administration and the military, bonuses are offered to psychologists who have board certification (Dattilio, 2002).

Recently, the ABPP began an Early Entry Option program that allows students enrolled in doctoral programs (as well as interns and postdoctoral fellows) to begin to bank a record of completion of each requirement for the ABPP at a reduced cost and without having to declare which specialty board certification they are planning to seek. The requirements for credentials review will be the same for all applicants, regardless if they seek the early entry option or not (ABPP, 2008).

### Examination for Professional Practice in Psychology and Practice Analysis

The Examination for Professional Practice in Psychology (EPPP), the national licensing examination for psychology, is offered by the ASPPB and administered through the Professional Examination Service (PES). First administered in 1965, the EPPP is developed with oversight by an examination committee appointed by the ASPPB (Terris, 1973). The examination was created for the purpose of assessing

the knowledge, understanding, and judgment deemed important to the practice of psychology (Terris, 1973). The EPPP sets a minimum standard for use for licensure with a set pass/fail point; it is not intended to identify excellence (Terris, 1973). The PES conducts periodic studies, or practice analyses, in which licensed psychologists in the United States and Canada are surveyed regarding the practice of professional psychology and the knowledge needed for such, in order to assess the validity of the content domains of the EPPP and update it as warranted. The ASPPB recently began a new practice analysis to update those done in 2003 and 1995. Of note, a focus of the current practice analysis will be to identify underlying professional competencies and to identify methods best suited to assess these.

### Linkages Between Education and Training and Credentialing/Regulatory Organizations

As Nelson (2007) notes, professional psychology education and training and credentialing/licensure systems developed independently of one another, although each continues to struggle with issues of quality assurance. Historically, there have been efforts by these two diverse communities to engage in shared conversations. Two examples of how this has occurred in formal context are the Council of Credentialing Organizations in Professional Psychology (CCOPP) and the CCTC.

The CCOPP was formed in 1996, in response to the establishment of a formal recognition process for specialties in professional psychology by the APA through the creation of the Commission for the Recognition of Specialties and Proficiencies in Professional Psychology (CRSPPP). The intent was to convene organizations to discuss the impact of specialty recognition on the profession and its education, training, and credentialing practices. It was hoped that the CCOPP could serve to promote open lines of communication and reduce policy conflict on issues of specialty and proficiency recognition, accreditation, and credentialing. The CCOPP was not formed as a decision- or policy-making entity independent from its member organizations. Rather, through shared expertise and information, it would serve to analyze, from different perspectives, issues that may have policy implications. Original membership in the CCOPP included credentialing and regulatory organizations in both the United States and Canada. To enhance the discussions, early in its history, a decision was

made to include liaison representation from the doctoral training councils, those groups formed for the purpose of organizing and promoting education and training within a specialty area of psychology (e.g., clinical, counseling psychology).

Further, the CCTC was developed to foster communication across diverse constituent groups within professional psychology's education and training communities, but to also include in the conversation representation from regulatory and credentialing organizations. The CCTC was formed in the mid 1980s. A mission statement was developed in the late 1990s that articulated the role of the CCTC in promoting discussion, encouraging communication, developing recommendations, and providing comment, thus providing a more active charge to the group beyond that of sharing information. Both the ASPPB and the National Register were active liaisons to the CCTC from its inception, and the CCTC has provided a unique context in which shared conversations occur among education and training groups and credentialing bodies (Nelson, 2007).

Recent events suggest that the exemplars of collaborative interaction among education and training groups and regulatory/credentialing bodies will continue and likely become more critical in the future. One key example was the recent ASPPB Practicum Task Force, noted in an earlier section. The ASPPB invited eight representatives from the education and training community, with expertise specific to defining and measuring competence, to attend the task force meeting and inform the discussion (ASPPB, 2008). This process helped to ensure that the proposed regulations used language and constructs consistent with models of professional psychology education and training. In addition, inviting representation from education and training was helpful in terms of achieving mutual acceptance of the product of such a working group, in that the education and training programs (for example, graduate departments and internship programs) would likely have to make changes to their existing program requirements and practices if they were going to enable their students to meet any changes in the requirements for licensure. Additionally, the ASPPB has made a formal commitment to establishing connections with the professional psychology education and training community by appointing a liaison to the major training councils (ASPPB, 2008b). The intent is to provide information about the licensure process to education and training groups, which would serve both students and the licensing boards by producing applicants better prepared to go through the steps of the licensure process.

One of the key forces driving this convergence is the continued and increasing conversations about the definition of and methods used to assess competence in professional psychologists. Although each community has had a longstanding investment in the construct, recently collaboration has expanded with the involvement of both groups in national initiatives such as the Competencies Conference (Kaslow et al., 2004) and the APA Benchmarks and Toolkit work groups (Fouad, et al., 2009; Kaslow, et al., 2009). As Nelson (2007) notes, "it is as common now as it was uncommon 30–50 years ago for those who represent these different roles and perspectives of professional responsibility to engage with one another in trying to address the challenges we face" (p. 8).

As the shift to a culture of competence moves forward in professional psychology education, training, and credentialing, the need for the assessment of competence must be infused throughout the sequence of education and training. This will ensure a best-practice approach to the assessment of competence. As Nelson (2007) notes, high-stakes summative evaluations, such as the licensing examination, must not only have fidelity with regards to actual practice, but also must reflect the education and training of the person being assessed.

## New Roles for Clinical Psychologists
### Health-service Provider
An emerging, or rather, increasing trend for clinical psychology will be expanded numbers of clinical psychologists providing services in health-care settings. Although psychologists practicing in health-care settings are not new, this trend represents an emerging opportunity for clinical psychology (Rozensky, 2008). Clinical psychologists seeking to expand their practice into health-care settings can benefit from the framework for this type of practice found in the literature of clinical health psychology, a long-established domain within the field that traces its roots back to 1969. A division of the APA representing clinical health psychology was formed in 1978. Clinical health psychology was recognized by the ABPP as a specialty in 1991, and by the APA in 1997 (Belar, 2008). Further, in 2001, the word "health" was added to the bylaws and mission statement of the APA, adding further emphasis to the roles that psychologists play in promoting health (Rozensky, 2008).

Clinical health psychology is recognized as a distinctive and encompassing specialty, and offers a definition of psychology practice that expands beyond that of a mental health profession to a health profession (Belar, 2008). Clinical health psychology focuses on both the psychological aspects of illness and treatment, as well as on the promotion of health and prevention of illness (Vandenbos, DeLeon, & Belar, 1991). Psychology's role in providing services in health-care settings has been expanding. Its influence is reflected in the development of special billing codes (known as health and behavior codes) specific to those psychological services provided to patients with medical problems but without psychiatric diagnoses (Belar, 2008). Models of education and training in clinical health psychology are well established, having first been articulated by the Arden House Conference in 1983, and the more recent competency model for clinical health psychology (France et. al., 2008).

In 1991, Vandenbos, DeLeon, and Belar noted the relevance of psychology's research and practice base to health-care settings and issues, and how this led to increased practice opportunities. Deleon, Kenkel, and Belar (2007) also noted the need and opportunity for psychologists to become more integrated into the culture of health-care settings, specifically primary care. Embedding education and training in community health centers offers exciting training opportunities, including working within the context of a team-based approach to health care, the opportunity for greater understanding of the unique skills and knowledge psychology brings to the health-care setting, and exhibiting how those who receive services benefit from such psychological interventions. Belar (2007) noted that psychology has a way to go to meet this opportunity with respect to educating and training a workforce prepared to function within health-care settings. She noted that about 10% of accredited psychology internship programs are in medical schools, and only about ten of the 375 accredited doctoral programs are in such settings. Belar (2007) urges psychology to expand research and training opportunities in those settings, with attention paid to training both future psychologists, as well to training individuals from other health-care disciplines to work with psychology.

An emerging role for psychology within the arena of health care is found within the sphere of public health (Rozensky, 2008). This represents a shift toward providing interventions that are prevention-based as opposed to treatment-oriented. Specifically, there are opportunities for the field to expand the range of services provided to the public health sector and make unique contributions. Rozensky (2008) notes that several of the leading health indicators listed in Healthy People 2010 are behavioral health issues that impact public health (e.g., physical activity, overweight and obesity; and tobacco and substance use). In addition, such a model of service delivery entails a population-based, community-oriented approach, an arena in which psychology has had relatively little involvement to date.

### Workforce Analysis and the Future of Clinical Psychology

Future roles for clinical psychologist depend on the extent and quality of information available about the workforce. Psychology has been debating for some time the societal needs for the psychology workforce, and in what types of settings psychologists are needed, at what numbers, and where emerging employment opportunities are located. A major reason that no definitive conclusions have been reached about the size and nature of the psychology workforce is largely due to the historical approach to data gathering conducted within the field. Isolated samples (snapshots) of the psychology workforce were taken as opposed to a comprehensive approach that integrates multiple sources of data across many venues and over time (Rozensky et al., 2007).

Robiner (1991) and Robiner, Ax, Stamm, and Harowski (2002) argue that, given the dramatic increases in the number of psychologists being trained and subsequently entering the workforce, it would only be a matter of time before the workforce would have more psychologists than needed. Robiner's conclusions were challenged by VandenBos, DeLeon, and Belar (1991), noting that psychology's increasing presence as a health-care profession had not been adequately accounted for. Further, employment forecasts for psychologists from the Bureau of Labor Statistics estimate that the need for clinical, counseling, and school psychologists will increase from approximately 167,000 in 2004 to 199,000 in 2014, a 19% increase; although these data do not include those earning a PsyD degree (Commission on Professionals in Science and Technology, 2006).

The employment picture in the academy suggests that faculty are being hired increasingly into part-time and\or non–tenure track positions (Barker & Kohout, 2003). For psychology specifically, a similar trend was observed from the mid 1980s to the late 1990s, in which part-time employment in

colleges and universities among those with doctorates in psychology has risen from 7% to 10%. The overall number of faculty with a degree in psychology increased from 18,730 to 19,320 between 1992 and 1998. Of those, the number with doctorates increased from 11,810 to 12,130, indicating that half of the new positions in psychology were for those with doctorates (Barker & Kohout, 2003). Those with a doctorate were also more likely to have a standard (regular, full-time) position. Women were just as likely to be in standard versus nonstandard jobs, whereas for men, standard employment was more likely. With regard to tenure-line positions, Barker and Kohout reported that 43.5% of those with doctorates were in positions or institutions that did not offer tenure, with an overall increase from 39.9% of positions being ineligible for tenure in 1992 to 44.5% in 1998.

The need to expand the number of ethnic minority faculty in psychology is a further significant challenge for the field. Faculty from minority backgrounds continue to be represented at low levels (approximately 11.5%), although this represents an increase from figures in the early 1980s (Barker and Kohout, 2003). This need was specifically addressed and identified as a priority for psychology by the APA Commission on Ethnic Minority Recruitment, Retention, and Training in Psychology (CEMRRAT; CEMRRAT2, 2007). Major findings included in their report are that ethnic minority representation has increased at all levels of psychology's education since the first report of the Commission, issued in 1997. However, the number of ethnic minority doctoral recipients increased by only 16.6% between 1996 and 2004; ethnic minorities received 20.1% of EdD and PhD degrees in psychology in 2004, and comprised 19.9% of new enrollees in PsyD programs in 2003. The report makes a series of recommendations to address the need to increase ethnic minority representation in psychology at all levels of the pipeline and to ensure this occurs, as well as to address the service and research needs to communities of color.

A workforce analysis is needed to provide comprehensive data and to accurately predict the future of the psychology workforce. Workforce analysis is an empirical approach that answers questions about the need for individuals trained within a discipline, and gives a full picture of the profession from entry to education and training systems to practicing professionals, and including those preparing to leave the workforce. This is done in the context of an environmental scan that identifies key societal issues and trends that will impact the need for professionals in a particular discipline. From the integration of these sources of data, a picture of the relationship between the numbers of available providers to need for providers can be discerned and predictions made about future workforce needs based upon societal need, educational requirements to meet those needs, and employment opportunities (Rozensky et al., 2007). Workforce analysis is a tool that is routinely used by other health-care professions, such as medicine, nursing, and pharmacy, to document need for training providers, as well to advocate for funding to develop the needed workforce (Rozensky et al., 2007). Psychology has recognized this need for workforce analysis through the creation of a newly funded Center for Workforce Studies within the APA, which is currently engaged in data collection as it relates to conducting a workforce analysis.

### National Health-care Policy Initiatives and Clinical Psychology

In the United States, at a national level, the broader health-care workforce has been the focus of attention, and key initiatives of relevance to clinical psychology will be noted in this section, as they suggest emerging roles for psychology in the context of larger health-care policy initiatives. In 2008, the Association of Academic Health Centers (AAHC), of which psychology is represented as a member through the APA, released a report, "Out of Order, Out of Time" (AAHC, 2008). The report calls attention to the critical need for a coordinated national health workforce planning initiative. A strong statement is made that health-care professions must work together to overcome the problems that have developed in the health-care system secondary to a decentralized approach to education and training, planning, development, and policymaking. The report recommends that stakeholders work together to make policy issues related to the U.S. health workforce a priority, to address workforce issues immediately in light of potential crises in workforce capacity and infrastructure, to move away from a decentralized approach to health workforce policy and instead adopt an integrated and comprehensive approach, and to create a health workforce planning body. The tasks of such a body would include developing a national health workforce agenda; working for greater consistency in standards and requirements for providers across jurisdictions; addressing issues of entry into the health professions and factors affecting the ability of

academic institutions to train the workforce; and confronting any inconsistencies among public or private policies, standards, or requirements that may have an adverse impact. The increased demands on the U.S health-care system in light of an aging population in need of and asking for health care, coupled with retirements from the health-care workforce outpacing entry by new professionals, argues for the importance and timeliness of such an agenda (AAHC, 2008). Psychology's involvement in such national initiatives is critical so that resulting policy actions will include psychology in its role as a health-care profession. Such inclusion will provide opportunities for continued and expanded roles for the profession within the larger health-care system, thus ensuring a strong future for the field.

Further, the need for policy that supports the development of a competent behavioral health-care workforce is a key recommendation of a report from the Annapolis Coalition for the Behavioral Health Workforce (Annapolis Coalition, 2007) titled, "An Action Plan for Behavioral Health Workforce Development." The need to focus on issues of both the supply and training of behavioral health workers is highlighted in this report. The Annapolis Coalition was commissioned by the Substance Abuse and Mental Health Services Administration (SAMHSA) with the charge to propose an action plan addressing these workforce needs that is both encompassing of the breadth of behavioral health and national in scope. The report notes evidence insufficient numbers of providers and a failure to train providers to address issues such as health promotion and prevention. Seven strategic goals are presented, addressing the need to broaden the concept of workforce, strengthen the workforce, and develop structures to support the workforce. The report of the Annapolis Coalition makes a strong statement in support of the need for national attention to mechanisms through which quality education and training can lead to increasing the numbers of skilled behavioral health professionals. Attention is given to the need for education and training to continue to promote models of competency-based education and training, and stresses that more collaboration across disciplines must occur to meet these goals of an adequately prepared and sufficiently large behavioral health workforce.

A final national initiative of significance to psychology is the report issued by the Institute of Medicine 2003, Health Professions Education: A Bridge to Quality (IOM, 2003). A key recommendation in that report is that, to promote quality in education and training across all health professions, five core competencies are required within each health-care discipline (IOM, 2003). These include the ability to provide patient-centered care, work in interdisciplinary teams, employ EBP, apply quality improvement strategies, and utilize informatics. Psychology must be in a position to coordinate its efforts across its training models, specialties, and regulatory bodies to incorporate such competencies into its education and practice if it wishes to be seen as part of the broader health-care community.

Reports such as these are routinely used to develop national policy initiatives that, in turn, may be used to advocate for support of existing or new educational and training programs and new clinical services, in order to realize the goal of the stated policy. Although psychology has established itself as a health-care discipline and is recognized in many national policy reports, the discipline must continue to advocate for its role in health-care settings through involvement in groups developing such initiatives and collecting the data used to inform the products of such policies.

**Conclusion**
Clinical psychology, as the largest doctoral subfield in the discipline of psychology in general and within professional psychology specifically, is engaged in efforts to ensure its future through enhancing quality in education, training, and credentialing, and in identifying and exploring new roles. Attention to quality, as demonstrated in the competence of clinical psychologists, is a major focus for both those in the education and training communities and those with credentialing or regulatory roles. Clinical psychology must address some challenges to its future, such as the difficulties students face obtaining doctoral internships, the high levels of debt incurred by students, and the complexity resulting from licensure laws that vary in their requirements across jurisdictions and the impact this has on both the initial credentialing and the mobility of psychologists. The emerging ability of the discipline to engage in workforce analysis is a key tool to better predict the future needs of society, so that the discipline can be responsive with education and training opportunities to prepare future generations to meet those needs. The future of clinical psychology is strengthened by involvement in federal policy initiatives looking at the need for increasing the health-care workforce and ensuring that those entering the workforce have the requisite skills to provide quality services.

### Future Directions

This chapter raises several questions as the clinical psychology profession looks to the future: How will clinical psychology respond to the growing emphasis on competency assessment in students and providers? In what ways might a competency-based approach be infused in the education, training, and credentialing processes? Can the growing collaboration between educators and regulatory groups be actualized in a sequential approach to competency assessment, one that is inclusive of the phases in professional development? How can the challenge raised by licensing laws that vary by jurisdiction, and the impact that this variability has on those entering the profession and those seeking mobility, be met? How will clinical psychology ensure its continued vibrancy by developing a workforce prepared for roles in emerging health care settings and public health? How can this approach be informed and enhanced by data obtained from a psychology or health-care workforce analysis? Finally, how will clinical psychology assure that workforce data and a competency-based approach to education and practice are utilized in national policy initiatives that support funding for education and training, as well as for clinical services provided?

# The Role of Psychology in Emerging Federal Health-care Plans

Antonette M. Zeiss *and* Bradley E. Karlin

**Abstract**

Professional psychology plays a prominent role at a number of key levels in the federal mental health-care system. This chapter examines the increasing impact professional psychology has had in recent years on two major and evolving federal mental health-care systems: the Veterans Health Administration (VHA) and the Medicare program. Within the VHA, professional psychology has helped to promote the expansion and transformation of evidence-based and recovery-oriented mental health care at the levels of policy, practice, and research. As the largest integrated health-care system in the nation, mental health-care transformation within the VHA and psychology's contributions to this major effort may help to inform other private and public mental health-care systems. Similarly, important changes within the Medicare program designed to promote mental health-care access, coverage, and quality portend that professional psychology will have an increasingly prominent role within Medicare. These developments provide unprecedented opportunities for psychologists to influence the future practice of psychology and the mental health-care landscape of the nation.

**Key Words:** Federal, Medicare, mental health, psychology, Veterans Health Administration

Professional psychology has had an increasingly important and diverse role in the federal mental health-care system in recent years. The federal mental health-care system in the United States is, in actuality, comprised of multiple systems that often interact but have significant distinctions in terms of their clinical landscapes, policies, and operations. Professional psychology has become a central component of each of these systems. In this chapter, we examine psychology's significant impact and expanding role in two major federal mental health-care systems: the Department of Veterans Affairs (VA) health-care system and the Medicare program. In recent years, psychology has had particularly profound growth and impact in the delivery of mental health care in the VA health-care system, where the profession has recently helped to foster mental health-care integration, interprofessional practice, recovery-oriented care, and service

innovation. In so doing, the profession has helped promote new models of mental health-care practice. Psychology has also been a critical part of mental health-care delivery in the Medicare program. Recent changes to Medicare, along with developments related to the implementation of health-care reform, will greatly increase psychology's stake in the federal health insurance program.

## Department of Veterans Affairs

VA is the largest employer of psychologists in the United States, as of the end of 2012, with over 4,100 psychologists employed at that time. Psychology is vitally involved in all aspects of health care for Veterans, including mental health care and health psychology care for those with medical illness without mental health diagnoses. Psychology also has important roles in VA research, education, and administration. Psychology historically has helped

to shape VA health care and policies, and it continues to do so as VA strives to provide evidence-based, accessible, sensitive care to all eligible veterans.

### VA as a Health-care System

The original incarnation of the agency now referred to as the "Department of Veterans Affairs" (VA) was established in July 21, 1930, as the "Veterans Administration." It was created to consolidate and coordinate government activities affecting war veterans. The mission of VA was expressed inspiringly by President Abraham Lincoln in his second inaugural address, speaking of military veterans of the Civil War: "With malice toward none, with charity for all, with firmness in the right as God gives us to see the right, let us strive on to finish the work we are in, to bind up the nation's wounds, to care for him who shall have borne the battle and for his widow and his orphan, to do all which may achieve and cherish a just and lasting peace among ourselves and with all nations" (Abraham Lincoln, Second Inaugural Address, Saturday, March 4, 1865).

Mental health services have always been a part of VA, but VA was a fairly small operation from its inception in 1931 until World War II led to dramatic expansion of VA benefits, including passage in 1944 of the Servicemen's Readjustment Act (P.L. 78-346), commonly known as the G.I. Bill of Rights, which authorized occupational, educational, and health assistance for veterans. VA became a cabinet-level department in 1989, and as such its title was changed to the Department of Veterans Affairs.

VA has many responsibilities, including provision of financial benefits such as pensions, educational funding support, and home loans. The specific focus in this chapter is on the Veterans Health Administration (VHA), the specific component of VA that is responsible for providing comprehensive health care to eligible veterans.

VHA is a complete health-care environment, offering the full spectrum of health-care services in a variety of settings. VHA's health-care system includes over 1,200 points of care. A total of 152 Medical Centers provide the full spectrum of care from primary care to tertiary care. In addition, over 800 community-based outpatient clinics provide primary care and outpatient mental health care in settings that are typically closer to the veteran's home than the nearest medical center. One-hundred thirty-five nursing homes (now called "Community Living Centers" in VA) serve older veterans and others who have significant physical disability and need extended care services. There are 300 Vet Centers, "storefront" operations that provide walk-in services in the community, provide readjustment counseling services to combat veterans and their families.

VA has over 320,000 employees, making it the second largest cabinet-level department. In the United States, there are 22.3 million veterans; of these, about 8.7 million veterans are enrolled with the VA system and at least 6.3 million enrolled veterans come for health-care services in any year. Of those receiving care for the year from October 1, 2013 through the end of September 2012, almost 1.8 million had at least one mental health diagnosis for which they were receiving care, including over 60,000 with posttraumatic stress disorder (PTSD) and 500,000 with an alcohol or other substance use diagnosis.

### History of Psychology in the Department of Veterans Affairs

Psychology has played a key role in VA since its early development. In 1945, soon after passage of the G.I. Bill of Rights, VA opened its first Mental Hygiene Clinic for outpatient mental health services at the Regional Office in Los Angeles. In that same year, General Omar Bradley, Administrator of the VA, appointed George A. Kelly, Ph.D., as the first VA psychology consultant, to help design the new VA psychology program. Kelly, who later developed personal construct psychology (Kelly, 1955), had accepted a post in the aviation psychology branch of the US Navy during World War II, and following the war, he taught briefly at the University of Maryland while also leading the development of psychology as an integral component of VA health care. Kelly was a consultant rather than a VA psychologist per se; during his period of consultation, James Grier Miller, M.D., Ph.D., was appointed the first Chief Clinical Psychologist for the Psychology Section in the Neuropsychiatry Division in VA Central Office (VACO).

Since then, there has been continuous psychology leadership in VACO. In 2011, for the first time a psychologist (Antonette Zeiss, Ph.D.) was appointed as the Chief Consultant for Mental Health Services (MHS) in VACO; this position had previously always been held by a psychiatrist. In 2010, a new Office of Mental Health Operations (OMHO) was created in VACO to complement the work of MHS, which focuses on mental health policy; OMHO has responsibility to ensure full implementation of policy throughout the VA system. The

first lead selected for OMHO is also a psychologist (Mary Schohn, Ph.D.).

There have been several professional organizations created for VA psychology. A main organization has been a section specifically for VA psychologists within Division 18 (Psychologists in Public Service) of the American Psychological Association; this section was created in 1977. Another organization also was created in 1977, known originally as the Association of VA Chief Psychologists. As the organization of VA health care changed in the 1990s, not all sites had separate psychology sections, and often psychologists were in other leadership positions not titled "Psychology Service Chief." In response to these changes, and because of an experienced need for mutual support and mentoring, that organization evolved into the Association of Veterans Affairs Psychology Leaders (AVAPL) in 1997. This organization is a freestanding association, separate from VA institutional lines of authority. Any psychologist with a leadership role of some kind in his or her facility, or in other contexts such as APA governance, is welcomed as a member. AVAPL has become a vital organization; their Web site (www.avapl.org) describes the organization as follows:

> The Association of VA Psychologist Leaders (AVAPL) is a non-profit organization with a voluntary membership of psychologists with various leadership roles within the Department of Veterans Affairs (DVA). Our purpose is to address the professional needs and concerns of VA psychologists. Our primary goal is to help provide the highest quality of patient care to our nation's Veterans. We are likewise committed to excellence in training and the advancement of clinical care through both program development and research.

APA has been a supporter and partner of VA psychology since the beginning of VA health care. As one example of such support, the Practice Directorate of APA has partnered with AVAPL since 1998 in offering an annual conference for VA psychology leaders; Division 18 of APA also cosponsors this conference. Similarly, VA has recognized and supported APA. VA members have taken key roles in APA governance, and VA psychology holds two meetings annually at the APA convention—a meeting of AVAPL psychologists, and an update by VACO psychology leadership. The APA accreditation process also has been valued by VA, as it ensures that psychologists have been trained in peer-reviewed, well-organized programs. Based on legislation passed in 1979, VA requires the following criteria to be eligible to be hired as a VA psychologist:

- US citizenship
- A doctoral degree in clinical or counseling psychology from a graduate school approved by the American Psychological Association (APA)
- An APA-approved internship
- State licensure or certification as a psychologist within 2 years of appointment

VA psychology thrived from the 1940s through the early 1990s. In addition to continuous leadership of psychologists in VACO, there was a growing number of psychology staff involved in an expanding array of clinical services, training opportunities, and research initiatives. However, in the 1990s, VA faced an array of funding and leadership challenges that affected psychology, as well as other mental health professions and programs. Figure 9.1 shows the decline in VA psychology staffing numbers from fiscal year 1995, a historic high point, to a low in 2000, with only minor increases up to the end of fiscal year 2003. Figure 9.1 shows the actual number of psychologists employed in VA across the Government Service (GS) grade levels (11–15) relevant for psychologists. The challenges in the mid-1990s to psychology affected mental health services generally. These challenges have been faced and overcome, beginning in the early years of the 21st century; we turn now to that story.

### VA's Implementation of Strategic Plans for Providing Mental Health Care

In 2003, VA recommitted to enhancing mental health services. The decline in VA's mental health-care resources was recognized by new top leadership in VA, including the Under Secretary for Health and the Chief Consultant for Patient Care Services. In addition, the emerging and projected needs for mental health care of new veterans from the war in Afghanistan and Iraq necessitated a revitalized system.

A catalyst and guide for designing a new approach to mental health care in VA came from the report of the President's New Freedom Commission on Mental Health (2003), titled "Achieving the Promise: Transforming Mental Health Care in America," released in 2003. This Commission did not focus on VA; its charge was to look broadly at mental health care in the United States. However, a VA ex-officio member attended meetings of the Commission, and VA took great interest in the findings as a guide—a road map—to how mental health care might optimally be organized and delivered.

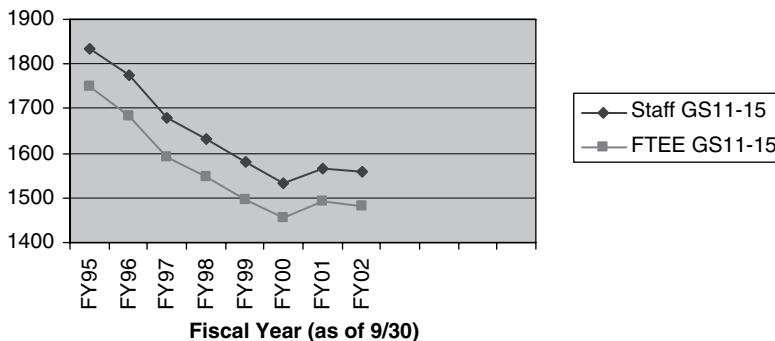
**VA Psychologists GS11-GS15 by Fiscal Year (FY), FY95-FY02**


**Figure 9.1** VA psychology staffing through fiscal year 2012

This Commission grappled with the current state of mental health care in the United States, and their report began with the sobering, but candid, words, "The system is fragmented and in disarray." The report went on to say, "To improve access to quality care and services, the Commission recommends fundamentally transforming how mental health care is delivered in America." Their recommendations for creating that transformation of mental health care in the United States were built around six goals:

Goal 1. Americans understand that mental health is essential to overall health.

Goal 2. Mental health care is consumer and family driven.

Goal 3. Disparities in mental health services are eliminated.

Goal 4. Early mental health screening, assessment, and referral to services are common practice.

Goal 5. Excellent mental health care is delivered and research is accelerated.

Goal 6. Technology is used to access mental health care and information.

In the fall of 2003, a VA work group was established to create an action agenda to implement the President's New Freedom Commission on Mental Health report as adapted to be relevant for VA. That work group's report, "Action Agenda: Achieving the Promise, Transforming Mental Health Care in VA," was released in December 2003 (Department of Veterans Affairs, 2003). The action plan then evolved further into a comprehensive strategic plan, the VA Mental Health Strategic Plan. The strategic plan was developed by an interprofessional group of mental health experts, with psychology

well represented among them. It was completed in 2004 and approved as official VA policy by the Secretary of the Department of Veterans Affairs in November 2004 (Department of Veterans Affairs, 2004). The strategic plan presented over 250 action items designed to enhance VA mental health care. These were organized into the same categories as the President's New Freedom Commission on Mental Health report but with content specific to revitalizing VA mental health care. For example, the plan presented actions designed to accomplish the following:

• Close gaps in VA mental health care, with the guiding principle that mental health care should be treated with the same urgency as physical health care.

• Transform VA's culture of care to one of psychosocial rehabilitation with a recovery orientation, moving beyond an emphasis only on symptom reduction.

• Integrate primary care and mental health services in VA.

• Provide care that integrates science and practice, resulting in delivery of evidence-based mental health care responsive to emerging research findings.

• Enhance suicide prevention activities.

• Provide accessible, timely services to meet the mental health needs of newly returning veterans from Afghanistan and Iraq.

VA made significant financial support available for implementation of the Mental Health Strategic Plan. Over the first 4 years of its implementation, federal government fiscal years 2005 through 2008 (October 1, 2004 through September 31, 2008), over $850 million cumulatively was committed

specifically to implement the strategic plan and enhance VA mental health services. This focused use of mental health enhancement funding was above and beyond the basic recurring VA mental health budget, which was over $3 billion in fiscal year 2008, and accelerated even further to $6.5 billion for 2013, as enhancements beyond the Mental Health Strategic Plan were developed.

As a result of progress made in implementing the Mental Health Strategic Plan, VA developed in 2008 a document designed to set policy defining the overall array of mental health services that must be available to any eligible veteran, regardless of the specific medical center or community-based outpatient clinic at which they received care. This was intended to ensure the availability of a broad continuum of accessible, evidence-based, and recovery-oriented mental health services for all veterans throughout the national VA health-care system. This document, the Uniform Mental Health Services Handbook in VA Medical Centers and Clinics (VHA Handbook 1160.01), became policy in the fall of 2008 and provides an aspirational definition of the full service mental health system that VA should provide. This visionary document can be viewed at http://www.mentalhealth.va.gov/providers/sud/docs/UniformServicesHandbook1160-01.pdf, and a version prepared to communicate the handbook's information to veterans and their families can be viewed at http://www.mentalhealth.va.gov/docs/MHG_English.pdf. The handbook provides guidance for local and regional VA health-care leadership in analyzing their current services in relation to the comprehensive requirements of the handbook, and it can be used to plan how to augment and reconfigure their current services to reach full adherence to the system of care delineated in it.

The document includes guidance on how programs should be organized, including leadership and governance (with full recognition of psychology as well as other specialty mental health professions), requirements for settings of care, including integrated mental health services in primary care and other medical settings, specialty mental health outpatient clinics, inpatient acute care, and residential rehabilitation programs. It lays out focused requirements for diagnostic groups, such as substance use disorder and PTSD care, and requirements for special emphasis populations, such as older veterans, who make up over 43% of VA patients receiving health care. While the handbook delineates what the overall system of mental health care must make available to veterans, decisions about how those services will be

utilized for the care of any specific veteran of course need to be made in active collaboration between the veteran and VA mental health providers.

VA has clearly turned around the decline in overall mental health care. Most of the additional funding provided for mental health enhancement has been used to hire new VA mental health staff. Changes in staffing levels for psychology provide a dramatic index of that overall turnaround. Figure 9.1 shows this for the data extending to the end of fiscal year 2012 (September 30, 2012), with a continual significant increase in psychology staff every year since 2004. The overall number of psychologists now employed in the Veterans Health Administration (as of the end of September 2012) is over 4,100, well above the prior historic high of 1,832 in 1995. With similar levels of hiring for other mental health professions, VA's overall total mental health workforce is now over 20,000 staff nationwide, a historic high point. Most significant is that these staff are increasingly devoted to implementing the kind of care envisioned by the Presidents' New Freedom Commissions on Mental Health, by VA's adaptation of it to the strategic plan, and by the Uniform Mental Health Services Handbook in VA Medical Centers and Clinics: care that is accessible and without major gaps, evidence-based, focused on recovery, integrated with primary care, including intensive suicide prevention efforts, and including services to meet the needs of returning veterans.

### Current Scope of Psychology Contributions to Mental Health and Overall Health in VA

VA care has been noted as excellent, leading it to be called the "best care anywhere," the title of a recent book by Longman (2010). An independent review of VA's mental health care (Watkins & Pincus, 2011; www.mentalhealth.va.gov/docs/capstone_revised_TR956_compiled.pdf) supports Longman's assertion. This review found, in relation to mental health care specifically, that:

> Comparison of VHA performance on nine selected administrative-data indicators with the same indicators assessed in a large, commercially insured population indicates that the performance difference is statistically significant for all nine measures. Average VHA performance was found to be superior for all of the assessment and medication-management indicators... Where average VHA performance exceeded private-plan performance, it frequently did so by large margins. (p. 146)

The report also notes, as has been internally documented in VA, that while VA mental health care is excellent, the system does not yet fully meet the high aspirational goals at all sites exemplified in the Uniform Mental Health Services Handbook; efforts to continue mental health enhancement are constantly ongoing.

Psychology's roles in the VA system have continued to be important to this record of excellence. The following sections describe some of the important contexts in which VA psychologists function. These span working as an integral team member in the provision of health care to Veterans, guiding and participating in research, providing training to the next generation of psychologists, and providing a variety of program development and leadership functions.

### VA Settings in Which Psychologists Provide Health Care

Psychologists in VA work in a wide array of health-care settings. Psychology has helped to promote mental health service innovation and to create new models of practice to ensure mental health services are consistently available. The system is designed to include provision of basic mental health services and also to create services appropriate for those who are in need but less likely to receive care, such as older veterans or homeless veterans.

Most settings are organized as interprofessional teams, with psychology functioning in a collaborative, integrated manner with health-care providers of other disciplines—physicians, nurses, social workers, pharmacists, physical therapists, and occupational therapists, to name just some of the participants. In these roles, psychologists respect the unique skills and knowledge of other health-care providers and seek to add value through the particular expertise of psychology.

The following list is a sampling of settings of care where psychologists play an integral role; it is not an exhaustive listing of all the settings and types of care to which psychologists contribute in VA.

#### INPATIENT AND OUTPATIENT MENTAL HEALTH

Psychologists in VA are well represented in traditional mental health-care settings: inpatient mental health units and outpatient mental health clinics. All VA medical facilities have outpatient mental health clinics, and most VA medical centers have mental health inpatient units. In addition, VA requires that mental health staff be available in all of its

emergency departments; these are based in medical centers, with the intensity of the emergency department coverage guided by the size and complexity of the medical facility. While it is not required that the mental health staff include psychology (or any other specific profession), psychologists commonly provide such emergency department coverage.

Most VA community-based outpatient clinics also provide mental health services, and larger clinics typically have at least one psychologist on staff. Those who do not may still provide psychology care through telemental health, in which a veteran at a VA community-based clinic is seen by a primary care provider or health technician, who arranges more complex mental health services to be delivered using secure televideo contact with a VA clinician at the medical center which has responsibility for the community-based clinic. In addition, many clinics are now able to provide televideo services from a VA staff member directly to the patient's home.

#### INTENSIVE OUTPATIENT MENTAL HEALTH CARE

Psychologists provide more specialized recovery-oriented outpatient care in a variety of VA intensive care settings. For example, Mental Health Intensive Care Management (MHICM) teams, based on the community Assertive Community Treatment (ACT) program (Dixon, 2000), have been shown to improve the ability of adults with serious mental illness (typically psychosis) to function in living, working, and participating in relationships in the community, with reduced likelihood of need for inpatient mental health hospitalizations. Another intensive outpatient program serving veterans with serious mental illness is the Psychosocial Rehabilitation and Recovery Center (PRRC) program. This is a transformation of the older Day Hospital concept; the new model is designed to be much more active in defining patient goals and promoting self-directed activity to reestablish community participation, with appropriate professional and peer support. Psychologists are staff members, and frequently team leaders, for these PRRC programs.

#### INTEGRATION OF PRIMARY CARE AND MENTAL HEALTH

VA has established model programs for integration of mental health into the primary care setting across the country. All VA primary care clinics are expected to complete such integration into patient-centered care teams (PACTs) that provide

primary care using a medical home, patient-centered model. VA requires these PACTs to include a mental health-care management component—typically a nurse who can follow psychoactive medication for depression or possibly other mental health problems—and additionally a co-located, collaborative mental health provider—commonly a psychologist. The co-located mental health provider is required to focus on at least depression, co-occurring anxiety, and problem drinking in the patients seen in primary care and to provide services in the primary care context for these concerns, referring only complex cases to specialty mental health. Typically, the role is much broader, as the collocated mental health provider assumes an active, collaborative role with the primary care provider.

VA screens all new patients in the Veteran's PACT for depression, PTSD, problem drinking, military sexual trauma, and traumatic brain injury (TBI). If either the depression or PTSD screen is positive, a clinician in the primary care setting is also required to evaluate suicide risk. Many of these screens are repeated at yearly intervals. Clearly, psychology can play a major role in conducting screening, following up on positive screens, establishing mental health care when needed, and determining when a referral to specialty mental health care is needed. The psychologist also provides consultation to primary care providers regarding the implications of any mental health problems for care of other health problems being followed in primary care. In addition, psychologists in the primary care setting often provide health psychology services, including psychological care for pain, sleep problems, stress management, and improved adherence to medical treatment regimens.

## POSTTRAUMATIC STRESS DISORDER

VA has, of necessity, been a leader in development of effective treatment for PTSD. Not all veterans who have experienced combat develop PTSD, but combat is a powerful stressor that clearly raises vulnerability. PTSD came into focus as a disorder after the Viet Nam war, although it has been recognized by some name after every war (battle shock, combat fatigue, "Soldier's Heart," etc.). VA offers outpatient specialized care for veterans with PTSD at every one of its medical facilities. VA also has a large network of inpatient and residential rehabilitation programs that allow more extensive care for those with more severe PTSD-related problems. As of 2013, VA's programs for women veterans with PTSD continue to expand, as more women veterans of combat returned from Iraq and Afghanistan and seek VA care.

In addition to clinical care, VA operates the National Center for PTSD (http://ncptsd.va.gov), a Congressionally mandated program to conduct research on PTSD and its treatment and to provide education and consultation throughout the VA system on care for PTSD, as well as to be a national resource for promoting effective treatment for PTSD outside VA. The National Center for PTSD has seven divisions across the country, each with a specific focus of activity. VA also has established in recent years, as a result of Congressional legislation, three additional Centers of Excellence for PTSD and other mental health concerns in currently returning veterans from Iraq and Afghanistan.

## EVIDENCE-BASED PSYCHOTHERAPY

Over the past 7+ years, VA has been working to nationally disseminate and implement evidence-based psychotherapies (EBPs) in its mental health-care system (Ruzek, Karlin, & Zeiss, 2012). Notwithstanding their effectiveness and recommendation in clinical practice guidelines, EBPs are largely unavailable in federal and other health-care systems. VA's EBP dissemination and implementation activities began in 2006 with the development of national, competency-based training programs in Cognitive Processing Therapy (CPT) and Prolonged Exposure Therapy (PE) to ensure that staff are available at every VA medical facility who can offer these therapies. These psychotherapies have the strongest evidence currently for their effectiveness in treating PTSD, compared to both current psychoactive medications and other psychotherapeutic approaches, according to the Institute of Medicine (IOM, 2007). These therapies are also recommended at the highest level in the VA/Department of Defense Clinical Practice Guideline for PTSD (2010). VA is funding training nationally in both these approaches. As of January 2014, VA has provided training in CPT and/or PE to more than 5,600 VA mental health staff. Program evaluation results associated with the CPT and PE training programs have shown that the training in and implementation of these therapies have resulted in significant, positive outcomes for therapists and patients (Chard, Ricksecker, Healy, Karlin, & Resick, 2012; Eftekhari et al., 2013).

Based on the success of the CPT and PE dissemination initiatives, VA has expanded its EBP dissemination and implementation initiatives to include therapies focusing on additional mental

and behavioral health conditions, including depression, serious mental illness, substance use disorders, insomnia, chronic pain, relationship distress, and motivation/adherence. Competency-based training programs for each of these therapies have been implemented. To date, VA has provided training in one or more EBPs to more than 8,000 VA mental health staff. These training programs have led to significant increases in therapist competencies and robust improvements in symptoms and quality of life. Psychologists have been leaders in all of the aforementioned activities. They lead clinical programs, they provide direct clinical care, they conduct research, and they are leaders in the National Center for PTSD and other VA mental health centers of excellence. In addition, psychologists have been leaders in the efforts to disseminate EBPs, and close to 3,000 staff trained to provide them have been psychologists.

### PSYCHOGERIATRIC CARE

A large number of veterans served by VA are older adults; as of 2008, 43% of veterans receiving care from VA were over age 65. Psychologists play important roles in geriatric care nationally (American Psychological Association, 2008), and the same is true in VA. Psychologists in VA have been key in developing innovative approaches to providing mental health care to older veterans, which is critical when considering that older adults are often highly unlikely to receive needed mental health care through traditional models of care (Karlin, Duffy, & Gleaves, 2008).

VA has pioneered an important health-care program to support veterans who are homebound because of illness and allow them to continue living at home. This program, Home-Based Primary Care (HBPC), goes well beyond community home health programs; it provides primary care, nursing care, rehabilitation care, social work, pharmacy, and mental health care, organized in a well-coordinated, interprofessional model of care. All team members meet regularly at the medical center that is their base, share assessment and treatment response information, and develop and refine treatment plans for these veterans continuously. All disciplines make home visits and support each other's efforts.

To promote mental health-care quality and access for veterans in HBPC, VA has integrated mental health providers into HBPC (Karlin & Karel, 2013). Every HBPC team in VA is mandated to include a full-time mental health provider, typically a psychologist. Serving as the HBPC Mental Health

Provider, the psychologist serves as a core member of the interprofessional HBPC team, providing a range of psychological and brief cognitive evaluation services, capacity assessments, evidence-based psychotherapy, behavior management services, caregiver and family-oriented interventions, and team-focused activities. Comparable to the other team members, the HBPC Mental Health Provider travels to veterans enrolled in the HBPC program and provides clinical services in the veteran's home. In addition, the psychologist provides consultation to other team members to improve their interactions and communications with patients to enhance the treatment process.

In addition, VA operates extended care settings, primarily for geriatric patients. These were termed "Nursing Home Care Units" until 2008, when the name was changed to "Community Living Centers" (CLCs), to underscore that the goal is to create a home-like, person-centered environment for older adults that nurtures as much independence and functionality as possible, while also providing the necessary level of nursing care and other health care. All CLCs were mandated in October 2008 to hire a mental health professional, also generally a psychologist.

Among the primary responsibilities of the CLC Mental Health Providers is to help serve as leaders in culture transformation in CLCs and to promote the delivery of evidence-based psychosocial services for behavioral and other neuropsychiatric symptoms associated with dementia or serious mental illness. There is a particular opportunity to bring these effective nonpharmacological approaches that have largely remained in the proverbial laboratory to the treatment settings and to reduce the use of antipsychotic medications which have been found to have a death risk associated with their use with older patients with dementia. The CLC Mental Health Provider also provides direct individual psychological and cognitive assessment and treatment services. Significantly, the rate of new episodes of depression for those moving from a home in the community to a nursing home has been estimated to be at least 50%. Such a high rate cannot be accounted for by the health status of those entering the nursing home care environment—much of it is the result of the depressogenic environment at many traditional nursing home settings (Zeiss, 2005). Psychologists can work with nursing staff and other providers in the CLC to transform the environment as envisioned in this new model, and as shown in prior research to be less mentally demoralizing (e.g., Bergman-Evans, 2004; Hamilton & Tesh, 2002).

Furthermore, psychologists have been leaders in developing and implementing the STAR-VA implementation initiative—an innovative initiative to promote nonpharmacological management of challenging dementia-related behaviors in VA. STAR-VA is an interprofessional intervention for managing challenging behaviors associated with dementia in residents of VA CLCs. STAR-VA was adapted from Teri and colleagues' Staff Training in Assisted Living Residences training program (STAR; Teri, Huda, Gibbons, Young, & van Leynseele, 2005), originally developed for training direct care workers in assisted living residences. STAR-VA was piloted in 17 VA CLCs; evaluation results indicated that the intervention was associated with significant reductions in the frequency and severity of challenging dementia-related behaviors and in reductions in depression and anxiety symptoms (Karlin, Visnic, McGee, & Teri, 2013). In light of these positive findings, VA is currently implementing an expanded STAR-VA implementation initiative, intended to at least double the number of CLCs where STAR-VA is provided as part of ongoing care.

Psychologists also serve older veterans in a variety of other settings: hospice, palliative care, geriatric primary care clinics, dementia clinics, and inpatient rehabilitation settings, for example for poststroke rehabilitation. Psychologist can offer direct clinical care in all such settings, and they also provide consultation to other interprofessional staff, particularly regarding mental health co-occurring disorders or when problem behaviors are exhibited. One area of great interest, but without a research base to guide care, is the experience of veterans with PTSD, often undiagnosed earlier in life, during late life, and in hospice care.

### RESIDENTIAL REHABILITATION

In addition to locked inpatient units, serving those with the most severe mental health problems, VA supports a large network of mental health residential rehabilitation and treatment program (MHRRTP) settings. Veterans live at these programs for weeks to months, while participating in intensive mental health therapeutic activities. Units are not locked and most medication is self-managed by the veterans while in the program. These programs are valuable for multiple populations, because they offer care in a secure environment for those who do not require and would not be willing to stay in a locked inpatient environment. They provide an intermediate step for those who need sustained care before returning to independent community living after inpatient care. They also offer the opportunity for more rural veterans to engage in intensive therapy while living at the medical facility, rather than having to travel long distances every day for intensive outpatient care. Psychologists are part of the staff at residential rehabilitation programs, they often have leadership positions, and psychologists participate in research and program evaluation focused on these programs.

### SUBSTANCE USE DISORDER AND DUAL-DIAGNOSIS CARE

VA provides a full array of substance abuse treatment services, including inpatient and outpatient detoxification support, intensive outpatient programs, MHRRTPs focused on substance use disorder, dual-diagnosis programs for those with other co-occurring mental health problems along with substance use disorder, care for problem drinking in the primary care team context, opioid substitution programs (using either methadone or buprenorphine), and individual and group treatment in outpatient clinics. Psychologists participate at every level of all these programs, as clinicians, administrators, researchers, and program evaluators.

### HOMELESS SERVICE

A major 5-year initiative to end homelessness among veterans began in 2011, with the goal of providing housing and necessary health and mental health services to all homeless veterans by the end of 2015. As of July 2013, there were estimated to be 62,619 homeless veterans based on methodology shared by VA and the Department of Housing and Urban Development (HUD). This number was down from prior years, with a 17.2% decline since 2009. Significant efforts continue to address homelessness in veterans.

Most homeless veterans have longstanding mental health and substance use problems, so services need to be more than finding housing; that is, the veteran needs to be linked to the full array of VA physical and mental health services. VA provides housing in multiple ways—through residential rehabilitation programs, including domiciliaries that specifically target the homeless, through nonprofit community-based transitional housing funded by VA through grant and per diem programs, and through a joint program of VA and HUD that provides permanent housing for veterans and their family members. VA also does extensive outreach to identify homeless veterans or those who are at risk of becoming homeless, for example because of recent

job loss or family changes, and encourages then to use these and other services. One outreach program involves "Stand Downs" annually at VA facilities, which are open houses where homeless veterans can get dental care, personal care (such as haircuts or clothing), and connect with other resources VA can provide. About 225,000 veterans who are homeless or at risk for homelessness are served each year by at least one service specifically designed to prevent or end homelessness.

Social workers have taken a lead role in VA in coordinating programs for homeless veterans, but psychologists have been very involved. In particular, psychologists are a key link between providing the basic social services needed and linking veterans to the right level of mental health care.

## MILITARY SEXUAL TRAUMA

VA defines military sexual trauma (MST) as "physical assault of a sexual nature, battery of a sexual nature, or sexual harassment." Sexual harassment is defined as "repeated, unsolicited verbal or physical contact of a sexual nature which is threatening in character." Experiences must have occurred while the veteran was on active duty or active duty for training. This definition is based on federal law (Title 38 USC 1720D). In this definition, sexual harassment and assault are conceptualized as experiences along a single continuum of sexual trauma (i.e., military sexual trauma). Recognizing that many survivors of sexual trauma do not disclose their experiences unless asked directly, it is VA policy that all veterans seen for health care are screened for MST. Data from VA's universal screening program show that approximately 1 in 5 women and 1 in 100 men have disclosed to their VA health-care provider that they experienced MST. Rates obtained from VA screening cannot be used to make any estimate of the actual rate of MST experiences for all those serving in the US military; they refer only to those veterans who have chosen to seek VA health care. A positive screen does not indicate the veteran's current level of distress, diagnosis, interest in, or need for treatment. Additionally, a positive response does not indicate that the perpetrator was a member of the military.

VA provides free care for the treatment of mental and physical health conditions related to experiences of MST. With regard to care available, every VA health-care facility has providers knowledgeable about treatment for the aftereffects of MST, and every facility provides mental health outpatient services for commonly associated disorders such as

PTSD, depression, anxiety, and substance abuse. In addition, many VA facilities have other services, among programs mentioned previously, for example, MHRRTPs. To accommodate veterans who do not feel comfortable in mixed-gender treatment settings, many facilities throughout VA have separate programs for men and women.

Psychologists are integral to providing MST-related care in VA. Psychologists are among the staff on the VA national MST Support Team, founded to conduct national monitoring of MST-related screening and treatment; to coordinate and expand national MST-related education, training, and veteran outreach; and to promote best practices in the field. The MST Support Team has assisted with the national dissemination of training to conduct CPT and PE for the treatment of PTSD, to ensure inclusion of materials relevant to MST survivors, and to promote attendance by clinicians working with MST survivors. Many clinical VA staff providing mental health care in relevant clinical programs also are psychologists, working along with social workers, psychiatrists, nurses, and other valued mental health staff.

## SUICIDE PREVENTION

Suicide prevention is the bottom line for all mental health care. Suicide prevention requires a public health approach, in which knowledge of suicidal risk is broadly disseminated and those at potential risk receive early care before a suicidal crisis develops. Suicide prevention also requires crisis care and specific clinical approaches that can be immediately, intensely available at the point where it is urgently needed. VA's overall plans for mental health care address both of these needs. The wide array of services defined in the Uniform Mental Health Services Handbook includes the public health approach to ensuring excellent basic services that prevent suicidal crisis. In addition, VA provides crisis care services, for those who do not seek earlier care, or who become suicidal despite clinical efforts. A major component of crisis care began in 2007 as a crisis hotline, available 24 hours per day, 7 days per week, staffed by mental health professionals. This has proven extremely valuable and continues to thrive and has expanded to include a Chat service and a Texting service, both of which also connect veterans with mental health professionals. In addition, a team of suicide prevention resource staff is available at every VA medical center and is responsible for veterans served by the facility and its community-based outpatient clinics. Psychologists

have been key in adapting and disseminating Safety Planning for Veterans, a brief intervention for suicidal patients, as well as in developing and providing training in suicide risk assessment.

### Services Provided by Psychologists

Considering all of the settings described earlier, VA psychologists offer the full range of services that professional psychologists are trained and licensed to provide. Of course, the relative level and the specific content of services vary by site and patient population. For example, the particular approach to assessment or the specific psychotherapy offered will depend on typical presenting problems, age, and other demographics of the veterans served in the setting.

Assessment roles are important for VA psychologists. VA employs neuropsychologists, who work in a variety of settings. Currently, the two components of the veteran population most in need of neuropsychological assessment are older veterans with cognitive changes ranging from mild cognitive impairment to dementia and veterans returning from active combat in Iraq or Afghanistan who have suffered traumatic brain injury. VA psychologists also conduct a wide array of other assessments. A computer-based system, the Mental Health Assistant, makes most well-validated personality and psychopathology assessment instruments available online. Patients can complete the instrument online and results are scored and sent electronically to the psychologist who ordered the test. Behavioral assessment, observing behavior in clinically meaningful situations, also is widely performed.

VA psychologists offer individual and group psychotherapy, using a wide array of techniques. Since 2007, VA has conducted, and continues to expand, comprehensive staff training programs to ensure wide availability of expertise in evidence-based psychotherapies. The evidence-based psychotherapies are required to be available to all veterans for whom they are relevant and clinically appropriate; the evidence-based psychotherapy may be sufficient to meet the needs of some veterans; for others, these therapies complement and support the delivery of other psychotherapy and medication-based therapy.

Psychologists working in medical settings, such as primary care setting, geriatric care clinics, and pain clinics, provide behavioral medicine services. In these settings, they typically work as an interprofessional team member, coordinating psychological care with medical and surgical care. Frequent targets of such services include chronic pain, sleep problems, problems with adherence to medical regimens, improved diet and other health promotion behaviors, and management of disruptive behavior in those with dementia.

Psychologists also play many roles in VA that go beyond direct service delivery. They are often leaders in design of new and innovative programs, usually working with other professions to design interprofessional service delivery. Because of the research and evaluation experience integral to psychology graduate training, psychologists also are very often the designers of evaluation components for new and existing programs. They can help VA facilities track data for required performance measures, such as meeting the requirement that any new referral for mental health care be evaluated and have treatment initiated within 15 days of the referral. Psychologists also often function as supervisors of other mental health staff in service delivery. Most VA sites have a lead psychologist who has professional oversight responsibilities for the other psychology staff at that facility and its community-based outpatient clinics. In addition, VA requires that any mental health leadership position—that is, a position that involves direct supervision of staff from multiple professions—be advertised for all of the core mental health professions. Thus, psychologists may also direct interprofessional clinical programs, having responsibility for effective program functioning and for direct supervision of multiple program staff. Finally, many psychologists function in key national leadership roles in the Department of Veterans Affairs Central Office in Washington, DC. The first author of this chapter served as the lead psychologist nationally for VA, in addition to being first the Deputy Chief for Mental Health Services (MHS) and then the Chief Consultant for MHS in VA Central Office until her retirement at the end of 2012. In addition, as of 2013, over 30 other psychologists had key roles in MHS or in other components of national leadership for VA.

VA psychologists also work in research settings. These include 10 Mental Illness Research, Education, and Clinical Centers (MIRECCs), which function collaboratively with an affiliated university to conduct research relevant to improving mental health care and disseminating important findings. VA has numerous other mental health Centers of Excellence established by Congress, including three specifically created to conduct and disseminate research relevant to mental health needs of veterans returning from Iraq and Afghanistan. Psychologists also play key roles in VA's National

Center for PTSD (NCPTSD). This Congressionally established program has seven divisions at different VA sites across the United States. As with the other Centers of Excellence, its mission is to conduct research—in this care, relevant to a better understanding of PTSD and improved treatment for it. The NCPTSD also conducts extensive training and consultation within VA on PTSD care and hosts a complex Web site with massive amounts of information on PTSD and its treatment. Finally, the NCPTSD is a national and international resource for promoting better understanding of PTSD and effective utilization of that understanding. In addition to these Centers of Excellence, VA funds and conducts a large amount of research through the Office of Research Development; many VA psychology staff obtain research funding from this source.

### VA Training of Psychologists

VA supports a large and thriving training program for all health professions. One component of that program, the psychology training program, comprises the largest single source of psychology training in the United States. VA's internship and fellowship training programs have thrived for many years and recently have grown considerably. As of 2013, VA funds 578 psychology internship positions in 107 sites in 47 states plus Puerto Rico and the District of Columbia. Recent efforts have significantly expanded internship programs in rural areas. VA also funds 348 postdoctoral fellowship positions at 57 sites.

All psychology training sites are required to obtain APA accreditation within 3 years of obtaining funding. Training occurs primarily in clinical settings and is designed to prepare psychologists who will become part of the workforce that provides direct clinical care for "VA and for the nation." In addition, MIRECC and other Centers of Excellence train postdoctoral fellows in research on mental health care. Currently, VA trains 17% of all of the psychology interns in the United States.

VA benefits from committing significant resources to training. In recent years, 70% of new psychologists hired had received some VA training. The extensive hiring likely could not have been accomplished without the well-trained pool of new psychologists coming from VA's internship and postdoctoral programs.

In recognition of the importance of psychology training, in 2008 VA created a Psychology Training Council; Training Directors of all VA psychology internship and postdoctoral programs are members of this Council. The Chair of VA's Training Council is a member of the Council of Chairs of Training Councils (CCTC), participating fully in discussions with other Chairs, who are primarily from graduate programs. VA plays an important role in CCTC, for example in addressing important issues regarding the relationship between the graduate school level of training and internship and postdoctoral levels.

### Medicare

The Medicare program, established in 1965 by the Social Security Act, is the US federal health insurance program for individuals age 65 and older and for other Americans with certain disabilities. Medicare is administered by the Centers for Medicare and Medicaid Services, and it has four main components: (1) Medicare Part A, which provides hospital benefits and limited extended care coverage; (2) Medicare Part B, which is optional and covers outpatient medical and professional services; (3) Medicare Part C, also referred to as "Medicare Advantage," is an optional capitated program that Medicare beneficiaries may elect in place of Medicare Parts A and B, which are fee-for-service programs; (4) Medicare Part D, which became effective in 2006, is an optional program that provides coverage of outpatient prescription medications.

Medicare is very different than the VA health-care system in a number of significant respects. For one, Medicare is not an integrated health-care system. Thus, services are often highly fragmented. Medicare has also traditionally had high cost-sharing requirements for mental health services. These aspects of the Medicare program have contributed to significant mental health care access difficulties among Medicare beneficiaries. Medicare Part A provides coverage for inpatient psychiatric services up to a lifetime limit of 190 days. There is no such limit on psychiatric or medical care provided in general hospitals. Under Part B, Medicare reimburses outpatient psychological treatment services at a rate of only 50%, compared to 80% for general outpatient medical care services. This has greatly limited the practice and provision of psychological services to Medicare beneficiaries who often cannot afford the high copayment requirements. Moreover, the overwhelming majority of Medicare beneficiaries do not have supplemental "Medigap" insurance coverage which picks up the costs Medicare does not cover for Medicare-approved claims. Making matters worse, significant restrictions in funding for Medicaid (the government health insurance for indigent individuals) in many states have greatly

limited coverage of Medicare copayments and deductibles for individuals who are enrolled in both Medicare and Medicaid. Traditionally, Medicaid has covered Medicare cost-sharing requirements for mental health services of individuals dually eligible for both programs. The limited coverage of mental health services under Medicare and the decreasing availability of Medicaid funding have served as significant disincentives to the delivery of psychological services under Medicare.

Beyond limited reimbursement of psychological services, professional psychology's involvement in Medicare has been tumultuous. It was not until 1989 that psychologists became recognized as independent providers under Medicare and able to bill the government health insurance program. Although strongly advocated for and welcomed by psychologists, the granting of professional autonomy to professional psychology did not have nearly the anticipated impact in improving the role of psychology in Medicare. The cost-sharing requirements under Medicare have rendered psychotherapy and other psychosocial services prohibitive for many. It is partly for this reason that older adults continue to significantly underutilize mental health services (Karlin, Duffy, & Gleaves, 2008).

Psychology's role and routine practices in providing psychological services in Medicare are significantly shaped by local coverage policies, known as local coverage determinations (LCDs; formerly known as local medical review policies). By statute, services provided to Medicare beneficiaries must be "medically necessary." However, Medicare statutes do not precisely define what is "medically necessary" or delineate the specific services that may be provided; rather, this standard is operationalized by LCDs, which are developed by insurance companies who contract with Medicare to manage the daily administration of the Medicare program. These contractors, historically known as "fiscal intermediaries" under Part A and "carriers" under Part B, develop LCDs that are to be consistent with medical science and standard practice. Unfortunately, many contractors have developed LCDs related to psychological service delivery that have often been highly restrictive, variable from one contractor to another, and, in some cases, directly inconsistent with medical science and standard practice (Karlin & Duffy, 2004). As a result of such policies, many psychologists and other mental health providers have been denied claims. Moreover, professional psychology has historically been relatively absent in LCD development and revision processes, even though their input should be considered.

The good news is that the role of psychology and the state of psychological service delivery in the Medicare program has improved considerably in very recent years and will likely see unprecedented positive opportunities and developments in the years ahead. In 2002, Medicare adopted six new "Health and Behavior Assessment and Intervention" (H&B) CPT codes that significantly extend the role of psychologists and psychological services in Medicare. These new codes allow for the provision of behavioral health assessment and interventions for problems related to physical health conditions, in the absence of a mental illness.

In addition, there is real and unprecedented opportunity for incorporating mental health prevention and early identification into Medicare, in light of recent political, policy, societal, and program developments, as we have examined in detail elsewhere (Karlin & Humphreys, 2007). Such a development could transform where, when, and how psychological services are provided, as well as enhance public welfare and promote the status of the profession. Moreover, since Medicare typically sets the trend that the private insurance industry follows, the incorporation of mental health prevention and early identification could have impact well beyond Medicare. Significantly, Medicare has established coverage for tobacco cessation counseling and alcohol and drug screening and brief intervention. In a recent major policy development, Medicare CMS announced through its national coverage determination process (Karlin & Humphreys, 2007) that it will cover annual screening for depression for Medicare beneficiaries in primary care settings that have staff-assisted depression care supports in place to assure accurate diagnosis, effective treatment, and follow-up. This is a major development that will undoubtedly increase the number of older adults who seek and receive mental health care, given the significant underdetection of depression in older primary care patients and a tendency of primary care physicians and patients alike to attribute depression symptoms to natural aspects of aging or medical disease (Alvidrez & Areán, 2002; Tai-Seale, McGuire, Colenda, Rosen, & Cook, 2007).

One of the most significant changes to Medicare and mental health care since the creation of the government health insurance program over 40 years ago will soon be fully implemented and will, undoubtedly, promote interest, opportunity, and involvement of professional psychology in Medicare. After many years of unsuccessful legislative proposals, 2008 witnessed the passage of landmark legislation

that will establish mental health parity in Medicare. On July 15, 2008, the Medicare Improvements for Patients and Providers Act of 2008 (Public Law No. 110-275) was enacted over Presidential veto, calling for the gradual phasing down of copayment rates for outpatient mental health services from 50% to 20%, beginning in 2010 and continuing through 2014. As a result, outpatient psychological services will be much for affordable for millions of older adults and very soon will have cost-sharing requirements that are fully on par with those of general ambulatory medical services.

In addition to promoting the financial access to mental health services, the creation of mental health parity in Medicare may have profound secondary benefits. Specifically, mental health parity in Medicare may likely elevate the status of mental health and psychological services, thereby reducing stigma and increasing "psychological access" to services. Mental health parity in Medicare is likely to also increase psychology's participation in and impact on the government health insurance program. Moreover, the leveling of the playing field between physical health and mental health care in Medicare may help to reduce fragmentation and promote coordination of services.

Another significant development in Medicare that will likely bode particularly well for mental health care and, psychology, specifically, are planned changes to reform Medicare's contracting process to promote provider and beneficiary satisfaction, pursuant to a relatively obscure provision of the Medicare Prescription Drug, Improvement, and Modernization Act of 2003. Specifically, the Act required that Medicare replace carriers and fiscal intermediaries with which Medicare contracts to help administer the Medicare program with 15 Medicare Administrative Contractors that will administer both Part A and Part B claims. This is designed to reduce the number of LCDs, which is likely to promote consistency. The final FI and carrier contracts are scheduled to end by September 30, 2013, and MAC contracts are planned to be fully implemented by October 31, 2013.

Looking to the future, there is writing on the wall to suggest that the psychological service landscape in Medicare may look somewhat different than it has traditionally. In recent years, CMS has implemented a number of "Pay for Performance (P4P)" initiatives within Medicare to promote improved quality of care of Medicare beneficiaries and enhance efficiency of care. These initiatives tend to focus on services for patients with chronically ill

conditions. Given the nature and scope of the current initiatives and some evidence of success, it is reasonable to believe that CMS's increasing focus on performance and outcomes will soon impact how mental health services are provided in Medicare, especially given the expansion in the mental health benefit in Medicare that parity will provide.

Finally, the implementation of the Affordable Care Act (ACA) is likely to have important impact on mental health-care delivery within and outside of the Medicare program. First and foremost, the ACA will increase access to mental health services for many individuals who currently have little or no insurance for mental health care. Second, the ACA will, like the increasing focus of Medicare, promote emphasis on service effectiveness, as the Act requires that covered services be safe and effective. Third, for Medicare beneficiaries, the ACA will close the so-called Medicare Part D "donut hole," or coverage gap, that exists for covered drug expenditures between $2,970 and $4,750 in 2013. Research has demonstrated that individuals reduce medication use when they reach the donut hole. The elimination of the donut hole will be phased in through 2020 (Polinski, Kilabuk, Schneeweiss, Brennan, & Shrank, 2010). The greater affordability of medications may increase medication use and medication-related services that may promote adherence and referral to psychotherapy and other psychological services. In addition, the ACA establishes a free annual wellness visit for Medicare beneficiaries and increases focus on health promotion that may promote opportunities for mental health detection, referral, and brief intervention.

## Conclusion

Psychology plays key and growing roles in national health care throughout the Veterans Health Administration, the component of the Department of Veterans affairs that provides health-care services. After a period of struggle in the 1990s and very early 2000s, psychology has thrived, with increased numbers hired, increased involvement in diverse clinical and research settings, and increased training positions. Typically, psychology functions as part of interprofessional provision of care in VA facilities, offering the full range of psychological services that are well coordinated with the services of other health-care professions.

At the same time that professional psychology experienced a period of decline in VA in the 1990s, psychologists faced significant challenges in the Medicare program, shortly after gaining recognition

as independent providers in Medicare. The granting of professional autonomy to psychologists in the late 1980s was a watershed moment for the profession; however, psychologists and patients confronted significant mental health-care access and reimbursement challenges in the ensuing decade that prevented psychology from fully achieving the possibilities that being part of the government health insurance program offered. Now, approximately 20 years after becoming recognized by Medicare, psychologists face a new dawn on the horizon. New regulatory and legislative changes in the Medicare program, including the expansion of the Medicare mental health benefit and increasing focus on screening and early intervention, provide unprecedented opportunities for psychologists—changes that, coupled with the mental health-care reform yielded by the Affordable Care Act, may dramatically shape the practice of professional psychology.

## Future Directions

1. Can VA expansion generally, and specifically for psychology, be sustained in the current economic climate?

2. What can mental health care in the United States learn from VA's experiences with dissemination of evidence-based psychotherapy?

3. What impact will the reduction in Medicare's outpatient mental health cost-sharing requirement have on utilization of psychological treatment services by older Americans?

4. How can psychology in VA and Medicare continue to innovate and respond to new research findings, as mental health care continues to evolve?

5. How can behavioral health service delivery be enhanced in VA and Medicare?

6. Will the Affordable Care Act lead to increased use of mental health services and to enhanced care coordination?

# Ethical Issues in Clinical Psychology

Kenneth S. Pope

## Abstract

This chapter examines how ethical issues are approached differently by two prominent psychological associations, how they are encountered by psychologists, the formal complaints they give rise to, and how they can be approached systematically to avoid missteps. Included are basic assumptions about ethics; the unique approaches to developing a ethics code taken by the American Psychological Association (APA) and the Canadian Psychological Association (CPA), and what each of these two codes provides; empirical data about what ethical problems psychologists encounter and what formal complaints they face; four major sets of ethical issues that are particularly complex and challenging (confidentiality, informed consent, competence, and boundaries); an area of major controversy (clinical psychology and national security); steps in ethical decision-making; and four possible lines of future research.

**Key Words:** Boundaries, competence, confidentiality, ethics, ethical decision-making, formal complaints, informed consent

*You're screening a patient for whom treatment is desperately needed and may be literally life-saving. However, her health insurance covers a very limited range of diagnoses. The only way she can afford treatment is for you to provide a false diagnosis.*

\*\*\*

*The clinic director instructs you to begin using a new battery of psychological tests, developed by his cousin, to screen all new patients. You diplomatically suggest that the clinic might use other tests, because the battery's tests have not been studied and lack validity and reliability data. The director refuses to rescind his order. You and your family live in a tight job market, you are unlikely to be able to find another position, and you are already barely able to pay the rent.*

\*\*\*

*During your dream internship, you work under the supervision of a famous psychologist, seeing patients as part of his large study. One day, you happen to see on*

*a secretary's desk the reports filed with the granting agency. Your supervisor has reported that you have been seeing over twice as many patients as you've actually seen. During a subsequent private discussion, when you raise the issue, your supervisor assures you that you were mistaken and that should you spread libel, not only would you face a lawsuit but that it would be impossible to certify your internship hours or write you the planned glowing job recommendation. The next day, a letter informs you that, due to unexpected new funding sources, your internship stipend had been doubled.*

\*\*\*

*When you arrive at your psychological services clinic, Department of Homeland Security officials are waiting for you. They believe there may be bombings planned for your area, and one of your therapy clients likely has specific information about when and where the bombs would be placed. The officials must have immediate access to your client's records, so that they*

*can be faxed to the field office to assist in investigation and interrogation. They also want to know anything you can tell them that might help them quickly obtain information from your client. They instruct you not to tell anyone, including the client, of this matter.*

\*\*\*

*Exhausted as you prepare to the leave your office and—already late!—rush to the airport, so that you don't miss the flight that will carry you and your family to that long-awaited vacation, you discover that your patient has left a message for you in an envelope taped to the outer door of your office: Convinced he will never find work to support his family, he is taking steps to end it all tonight.*

\*\*\*

*A new teenage patient tells you that her father got drunk and sexually assaulted her, but that if you tell anyone she will deny it, tell them that you made it up because she had refused to have sex with you, and then kill herself. You believe her.*

Each day clinical psychologists confront almost countless ethical issues, from the routine to the one-of-a-kind. They range from the trivial to matters of life or death. Responding to the almost infinite variety of these issues is an essential, inescapable part of the work. This chapter examines the ethical aspects of clinical psychology.

The first section following this introduction makes explicit some basic assumptions about ethics. Because ethical decision-making occurs in the context of a formal code of ethics, the second and third sections of the chapter describe the unique approaches to developing such a code taken by the American Psychological Association (APA) and the Canadian Psychological Association (CPA), and what each of these two codes provides. The fourth section presents empirical data about what ethical problems psychologists encounter and what formal complaints they face. The next four sections focus on major sets of ethical issues that are particularly complex and challenging: confidentiality, informed consent, competence, and boundaries. The final section presents a set of steps that clinical psychologists may find helpful when thinking through ethical decisions.

## Basic Assumptions

Too often "ethics" may come across as a dry or forbidding abstraction. A heavy coat of misleading stereotypes can hide its nature. It may seem a set of authoritarian do's and don'ts to be passively followed or mechanically applied; a set of answers "out there" somewhere, if we can only find the right one at the

right time from the right source (a book, an attorney, someone on an ethics committee). Ethics may seem a nightmarish area in which an angry patient can file a baseless complaint against us and we will have to defend ourselves against a potentially hostile ethics committee while colleagues wonder if we've done something horrible; or ethics may be a way to protect ourselves, by burying our work under layers of risk micro-management and psychology's version of "defensive medicine." The following basic assumptions, which are adapted from Pope and Vasquez (2010), are intended to sweep away some of these misconceptions:

• Responding effectively to ethical issues is a process of active, creative decision-making rather than passive rule-following or finding some book or expert to tell us what to do. Ethics codes, administrative regulations, legal requirements, and those with expert knowledge of these documents can inform our decisions, but they cannot make those decisions for us. They may underscore essential responsibilities, such as informed consent, but they cannot identify how each of us—with different patterns of skills, theoretical orientations, and resources—can best meet those responsibilities with diverse patients from diverse backgrounds, each with different patterns of strengths, weaknesses, and clinical needs. Codes, regulations, requirements, and authorities cannot do our thinking for us.

• Sound ethical decision-making depends on maintaining awareness of the ethical implications of what we do. The rush of events—the next patient, phone calls to return, and overdue paperwork—can distract us. Fatigue, financial pressures, family conflicts, worries about the future, and so many other stresses can dim our awareness. None of us is immune to these factors.

• None of us is perfect, so our decisions are often imperfect. We must make some ethical decisions on the basis of inadequate information, perhaps lacking adequate time, resources, and options. Despite limitations, we are individually responsible for doing the best we can, and we must assume personal responsibility for our actions. In light of our fallibility, it is always worth asking ourselves: Can I come up with a more creative, effective approach to this ethical issue, one that better serves those who are affected?

• Our ability to identify the approach that makes the most sense ethically, practically, and

clinically depends to some extent on maintaining awareness of evolving research, theory, and practice. No matter how authoritative, widely accepted, or consistent with our expectations, the claims emerging from scientific and professional articles do not deserve passive or reflexive acceptance, but warrant thoughtful, informed questioning and active engagement.

• Sound ethical decision-making may often be consistent with sound risk-management, but ethical decision-making is different from risk-management and may lead clinical psychologists to consider placing their income, reputations, referral sources, jobs, or psychology licenses at risk. A classic article, "The Psychologist As Whistleblower," documented how a psychologist's steadfast refusal to follow instructions to quickly discharge patients from a Veterans Administration program because he believed precipitous discharge would endanger their health and safety ultimately led to his being fired (Simon, 1978). Pope and Gutheil (2009b; see also Pope & Bajt, 1988) discussed the implications of the APA ethics code's approach to risks that arise when psychologists encounter laws that are in conflict with their ethical responsibilities.

• All of us have ethical blind spots, and the respectful, direct intervention of colleagues can save us from making or compounding ethical blunders. We are valuable resources for each other. However, most of us probably find it more interesting and convenient to question our colleagues' ethical beliefs, reasoning, or behavior than our own. We need to spend at least as much time, energy, and creativity—probably more—in questioning our own thoughts and actions as we do in challenging others.

• When questioning ourselves, it is probably easier to focus on those things we aren't so sure of, assumptions and conclusions we have not developed a strong allegiance to, ideas and possibilities we are still trying on for size. It can be equally important—and often more revealing—to question that which we have always taken for granted, which we are most sure of, or which seems beyond question. This form of rigorous questioning often takes considerable courage, sometimes raising possibilities that may be exceptionally unpopular and viewed by ourselves and others as taboo, "politically incorrect," or "psychologically incorrect" (Pope, Sonne, & Greene, 2006).

## The American Psychological Association's Approach to an Ethics Code

The APA existed for 60 years without an ethics code. Early accounts trace the APA's founding to a July 8, 1892, organizational meeting attended by Stanley Hall, George Fullerton, Joseph Jastrow, William James, George Ladd, James Cattell, and Mark Baldwin at Clark University (Fernberger, 1932). It is worth noting that a psychologist writing a history of the organization attempted to gather and verify information about this meeting. Finding that two of psychologists who allegedly attended the meeting (Cattell and Jastrow) denied attending, and unable to locate any supportive evidence, he concluded that there is no evidence that the meeting actually occurred and that "all of this leads to a possible conclusion—and I say this as an ex-Secretary of the Association—that one cannot always trust the printed minutes . . . as evidence of what actually happened at any meeting" (Fernberger, 1943, p. 35).

Whatever its actual beginnings, the APA created its first Committee on Scientific and Professional Ethics (CSPE) several decades later, in 1938. When someone made a formal complaint about an APA member, the CPSE discussed the matter privately and attempted to agree on an informal approach to resolving the matter. Working without a written ethics code, the CPSE had to reach of consensus and then rely on persuasion.

The initial ethical challenges encountered by APA members were neither varied nor complex. Rich wrote that ethical problems in the APA's early years were fairly simple because the organization's membership consisted mainly of college professors. "The only ethical problems which seemed to present themselves were those of plagiarism and of academic freedom" (1952, p. 440).

However, as the ethical problems grew in diversity and complexity, the APA charged the committee, in 1939, with assessing whether an ethics code would be helpful. Eight years later, the CPSE concluded that the APA needed a written code, in part because an "unwritten code is tenuous, elusive, and unsatisfactory" ("A little recent history," 1952). The APA created a Committee on Ethical Standards, chaired by Edward Tolman, to develop an ethics code for psychologists.

Not all members thought that an ethics code was a good idea. Various members—some of them exceptionally prominent—argued vigorously against the APA adopting a written code of ethical standards. Calvin Hall, for example, believed that even the

most carefully developed written code of ethics favored the crooked psychologist, who examines an ethics code "to see how much he can get away with . . . and since any code is bound to be filled with ambiguities and omissions, he can rationalize his unethical conduct" (Hall, 1952, p. 430).

The CPSE recommended a method for developing an ethics code that was remarkable and unprecedented, sharply different from the customary and accepted methods used previously by more than 500 professional and business associations (Hobbs, 1948). They wanted to avoid what Hobbs termed the "armchair approach" (p. 82) in which a committee of those presumably most qualified would study the available codes, pressing issues, and relevant literature; then issue general calls for input or comments in various publications, but not contact members individually.

They decided that the code's development must be based on the methods of psychological science, specifically empirical survey research. The APA would contact its members individually, sending each a letter that would ask about the psychologist's personal experiences. This method of reaching out to members individually could establish a direct connection between the committee and each member that would be more effective than running a general announcement in some of the APA publications that members might or might not happen to notice. It conveyed the seriousness with which the committee was seeking input from all members, rather than the relative few who participated actively in the APA, and the weight that the committee accorded to each member's individual views. Contacting the members individually and asking for personal experience would give all members, rather than just a sampling of the membership, a stake in the code. Members would know that their views and experiences were part of the *primary* data on which the code was based. Nicholas Hobbs wrote that this method would produce "a code of ethics truly indigenous to psychology, a code that could be lived" (Hobbs, 1948).

The APA adopted the CPSE's recommendation and appointed a new committee, chaired by Hobbs, to conduct the research and create a code (APA, 1949). Each of the 7,500 APA members received a letter in 1948. The letter invited the member "to share his experiences in solving ethical problems by describing the specific circumstances in which someone made a decision that was ethically critical" (APA, 1949). More than 1,000 critical incidents became the empirical base of APA's first ethics code. The committee assessed and categorized the responses,

and began publishing the results of their work in 1950.

The APA Board of Directors had asked the committee to address what they believed to be an urgent concern: the growing number of psychological tests and other assessment instruments that were questionable in terms of validity and reliability, along with the increase in psychologists and others who were conducting psychological assessments but who lacked appropriate education, training, and experience. Noting that, in 1944 alone, around 20,000,000 U.S. citizens took around 60,000,000 psychological tests, the committee produced a set of 18 "Ethical Standards for the Distribution of Psychological Tests and Diagnostic Aids," which the APA quickly adopted (APA Committee on Ethical Standards, 1950).

In 1951, the committee published six separate sets of draft ethical standards, each accompanied by relevant critical incidents (APA Committee on Ethical Standards, 1951a,b,c,d). The six topic areas were:

- Ethical standards and public responsibility
- Ethical standards in professional relationships
- Ethical standards in client relationships
- Ethical standards in research
- Ethical standards in writing and publishing
- Ethical standards in teaching

After extensive discussion and several revisions, the APA adopted its first ethics code in 1952 and published it in 1953 (APA, 1953). Amazingly—at least from the perspective of subsequent revisions—the first code ran 171 pages!

The APA adopted nine subsequent revisions of the code in 1959, 1963, 1968, 1977, 1979, 1981, 1990, 1992, and 2002, although in 2010 APA Council voted to change several sentences in the Introduction and sections 1.02 and 1.03 that were relevant to the Nuremberg Ethic ("Amending the Ethics Code," 2010). The Nuremberg Ethic and its relationship to the APA ethics code is discussed in a subsequent section of this chapter, "An Area of Major Controversy: Clinical Psychology and National Security."

The latest version of the APA ethics code includes an introduction, preamble, five general principles, and specific ethical standards. The preamble and the general principles—which include beneficence and nonmaleficence, fidelity and responsibility, integrity, justice, and respect for people's rights and dignity—are nonenforceable aspirational goals to guide psychologists toward the highest ideals of psychology. The subsequent 89 ethical standards are enforceable

rules for conduct. The ethical standards fall into ten major categories:

- Resolving ethical issues
- Competence
- Human relations
- Privacy and confidentiality
- Advertising and other public statements
- Record keeping and fees
- Education and training
- Research and publication
- Assessment
- Therapy

Each revision of the code was to be based on similar surveys mailed to the membership to gather "additional critical incidents of controversial behavior" (Holtzman, 1960, p. 247). By sending an individual survey form to each member, as was done with the original code, subsequent revisions would maintain this unique empirical approach, preserve the stake that *all* members had in a code, reflect the concerns and expertise of the full range of membership, and foster loyalty to the code.

The conviction that revisions should be based on survey forms sent to the membership also rested on beliefs about empowerment, management style, group process, and allegiance (e.g., Golann, 1969; Hobbs, 1948; Holzman, 1960). The two ways of developing a revision were considered to create very different outcomes. The first approach, unique to psychology, began by actively seeking, through a formal mail survey, the observations, ideas, and questions from those working "on the front lines" in diverse specialties, settings, and circumstances. These survey responses form the primary data for the revision. The second approach, used by virtually all other professional and business associations, centered on the work of a committee that would use many sources of data, perhaps including a published call for input or a survey of a sample of the membership. The first approach was considered (a) to empower all members by involving them meaningfully and individually (through the mailed survey) from the start, (b) benefit from better group or organizational dynamics by creating a psychological sense of community among all members, and (c) produce a better revision.

The most valuable attribute of the APA's empirically based code of ethics was that it was "based upon the day-to-day decisions made by psychologists in the practice of their profession, rather than prescribed by a committee" (Golann, 1969, p. 454). Surveying all members individually was considered

essential to maintain an ethics code "close enough to the contemporary scene to win the genuine acceptance of the majority who are most directly affected by its principles" (Holzman, 1960, p. 250). To date, none of the revisions of the APA's ethics code has been based on crucial incident survey forms sent individually to the full membership.

## The Canadian Psychological Association's Approach to an Ethics Code

The CPA was formed in 1939, and existed for over two decades without a formal ethics code. Incorporating under the Canada Corporations Act, Part II, in 1950, the organization represented the relatively small number of Canadian psychologists scattered across a very large country. As the need for a formal code became apparent, so did the daunting challenges of bringing together psychologists from diverse regions often enough to develop the basis, methodology, organization, and wording of a formal code. Consequently, CPA chose "to adopt the 1959 . . . APA code for a 3-year trial. This was followed by adoptions (with minor wording changes) of the 1963 and 1977 APA revised codes" (Sinclair & Pettifor, 2001).

CPA members soon began to grow discontent with the APA code, but it was only in 1977, when the APA released that year's revision of the code, that the discontent reached a critical point (Sinclair, N. P. Simon, & Pettifor, 1996). A central concern was that the APA's new code ran "ran the risk of changing the nature of the professional relationship from a primarily fiduciary contract to a commercial one" (Sinclair et al., 1996).

Sinclair (1998) notes that the CPA established four goals for its new code:

- Conceptual coherence, which would make it better suited to use in education
- Inclusiveness, so that it would embrace more new areas of psychological practice
- Explicitness, so that it would provide clearer guidelines for what to do when two or more ethical values were in conflict
- Usefulness, so that it would include helpful rules for the ethical decision-making process

To provide an empirical basis for the code, the CPA sent 37 ethical dilemmas to its members (Truscott & Crook, 2004). The dilemmas were designed to cover each of the principles—and the conflicts among those principles—in the APA's current code, as well as newer areas of practice including creative approaches that as yet lacked

empirical support. The survey not only invited participants to describe what they would do when confronting each dilemma but also asked them a series of questions created to clarify the ethical decision-making process that led up to that action. A content analysis found that the participants were relying on four fundamental ethical principles (Canadian Psychological Association [CPA], 1986):

- Respect for the dignity of persons
- Responsible caring
- Integrity in relationships
- Responsibility to society

The CPA's first ethics code set forth those four principles, and included a set of seven steps for ethical decision-making. The CPA adopted the most recent revision of the code in 2000. The third edition of the Canadian Code of Ethics for Psychologists (CPA, 2000) includes a preamble, four ethical principles, statements of values that are embodied in each of the ethical principles, ethical standards that show how the principles and values are applied to psychologists' activities, and a set of ten steps in ethical decision-making. (Note: A subsequent section of this chapter discusses steps in ethical decision-making.)

The current code also includes sections discussing:

- The code's uses
- Nine specific responsibilities of the individual psychologist (e.g., to discuss ethical issues with colleagues regularly; to take seriously the concerns of others about one's own ethically questionable behavior; to avoid being provocative or vicious when voicing or responding to concerns about ethically questionable behavior)
- The code's relationship to personal behavior
- The code's relationship to provincial regulatory agencies
- Definitions

### Empirical Data About What Ethical Problems Psychologists Encounter and What Formal Complaints They Face

This section reviews some data that shed light on which ethical dilemmas psychologists seem to face most often and what ethical issues are the most frequent sources of formal complaints against psychologists.

### Ethical Incidents That Are Challenging or Troubling

Fifty years after the original membership survey that formed the basis of the APA's original ethics code, a limited replication appeared in *American Psychologist* (Pope & Vetter, 1992). Because the survey was funded by two individuals without a grant or other external financial resources, the replication was limited to only a sample, rather than the full APA membership. A random sample of 1,319 APA members received survey forms asking them to describe incidents that they found ethically challenging or troubling. Over half (679) of the psychologists provided 703 incidents falling into 23 categories.

Here are the eight largest categories of critical incidents, along with examples of the incidents. The percentage of reported incidents in each category appears in parentheses.

- *Confidentiality* (18%):
  One of the psychologist's patients is a psychologist who tells the therapist he has committed an ethics violation but confidentiality prevents the therapist from reporting it.
  A clinic's executive director reads the charts of patients who are members of his church, saying that it helps him in his clerical role.
  One client tells the psychologist that she was raped but the police do not believer her because of a history of psychological problems. Another client tells the same psychologist how he raped that woman.
- *Blurred, dual, or conflictual relationships* (17%):
  The psychologist lives in a rural setting and must offer psychotherapy to other members of her tightly knit spiritual community because there is no one else to provide appropriate psychological services.
  A psychologist's patient, whom she had been working with for 3 years, fell in love with the psychologist's oldest and best friend. The psychologist obtained clinical, legal, and ethical consultations and, as a result, arranged a gradual transfer to another therapist and told her friend that she would need to suspend contact temporarily. She was currently considering when and under what conditions she could see the new couple socially.
- *Payment sources, plans, settings, and methods* (14%):
  The psychologist evaluated a young boy who had been severely sexually abused and was depressed. He recommended 6 months of therapy. However, the managed care company approved ten sessions to be conducted by a nonprofessional. The psychologist noted that there is no ten-session treatment for a young boy in such

circumstances that has shown evidence of effectiveness.

A managed care organization stopped coverage of therapy and advised the psychologist's patient to terminate. The organization then referred the patient to another therapist, whose managed care contract specified a lower fee.

The psychologist works for a private hospital that generally provides good clinical services. However, the motivation to maximize profits is so intense that it often overrules clinical concerns and results in decisions that harm patients. Patient complaints tend to be attributed to their psychopathology, and the psychologist feels he can't speak openly with his patients about the hospital's financial decisions overshadowing clinical concerns.

• *Academic settings, teaching dilemmas, and concerns about training* (8%):

The psychologist, who employs over 600 other psychologists, finds it disturbing that some of them have marginal ethics and competence, and that these problems were not addressed in graduate school and were no barrier to graduation.

• *Forensic psychology* (5%):

The psychologist describes a forensic psychologist in his community who is widely known (to lawyers and others) to give whatever testimony that the retaining lawyer requires. He has a great courtroom presence and is very persuasive. The side that retains him often wins because of his testimony, so that lawyers often hire him.

The psychologist describes another psychologist whose forensic assessment reports or testimony go far beyond the psychologist's competence or what the data support. The survey respondent does not know whether or how to handle the matter.

The psychologist is uncomfortable providing sensitive information about a client in a deposition or in court, even though the client has given informed consent for the testimony.

• *Research* (4%):

The psychologist is a co-investigator on a research grant who happened to see on a secretary's desk the principal investigator's interim report to the funding source. The report states that the current data were based on twice as many subjects as had actually participated.

The psychologist listed three concerns: a study that involved deception that was not disclosed; using a data video in a public presentation without the consent of one of the subjects in the video (the subject was in the presentation's audience); and performing an experimental manipulation in the assignment of course homework without informing the students.

The psychologist was consultant at a prominent medical school for drug research in which there were violations of random selection of participants.

• *Conduct of colleagues* (4%):

The psychologist referred a child patient to a community medical center for hospitalization, contacting a psychiatrist whom the mother wanted involved to make the arrangements. The psychiatrist hospitalized the child and then informed the psychologist that, as the admitting professional, he would take over the treatment and would assign the child to another psychologist who worked in his office.

The psychologist worked at a facility whose director had emotional problems that adversely affected patient care and staff morale. The director refused to seek professional help.

The psychologist sees foster children whose case workers have little time or interest in them. The psychologist does not know how to maintain effective working relationships with the case workers under those conditions.

The psychologist had trouble dealing with a fellow faculty member after many students complained about the colleague.

• *Sexual issues* (4%):

The psychologist's supervisee reported that her prior supervisor had forced her to perform sexual acts and had threatened to refuse to validate her supervision hours if she refused or reported him.

The psychologist's patient is a psychiatrist who has been having sex with his own patient for the past 6 years. He now would like to bring what he calls "the affair" to an end but is afraid of what will happen if he does.

The remaining categories and percentages were: assessment (4%), questionable or harmful interventions (3%), competence (3%), ethics (and related) codes and committees (2%), school psychology (2%), publishing (2%), helping the financially stricken (2%), supervision (2%), advertising and (mis)representation (2%), industrial–organizational psychology (1%), medical issues (1%), termination (1%), ethnicity (1%), treatment records (1%), and miscellaneous (1%).

### Sources of Formal Complaints Against Psychologists

Drawing on the annual data made available by the American Association of State and Provincial Psychology Boards, the APA, CPA, and the APA Insurance Trust, Pope and Vasquez (2010) presented multiyear data on ethics, licensing, and malpractice complaints against psychologists in the United States and Canada. These data suggest areas of particular difficulty for psychologists.

#### ETHICS COMPLAINTS

Ethics cases opened by the APA are assigned a primary category, which is the technical basis for processing that particular care. However, cases are also assigned "multiple categories," which indicate the underlying behaviors. For example, a case may be opened because a member was expelled from a state psychological association, so the expulsion would be the primary category. But the expulsion may have been based on sexual misconduct with an adult, working outside areas of competence, and a breach of confidentiality—the multiple categories. During a 5-year period, the multiple categories with the largest number of newly opened cases (with the number of instances appearing in parentheses) included: loss of licensure (92); sexual misconduct with an adult (59); inappropriate practice involving child custody (25); nonsexual dual relationship (24); inappropriate practice involving insurance or fees (18); other (nonspecified) adjudications in other jurisdictions (14); other (nonspecified) inappropriate professional practice (11); confidentiality (10); felony convictions (8); response to ethics committee (7); sexual misconduct with a minor (3); inappropriate response to a crisis (3); and inappropriate termination/supervision (3).

It is extremely rare that the CPA receives ethics complaints against its members. During the same 5-year period, the CPA had taken no action against any member.

#### STATE AND PROVINCIAL PSYCHOLOGY LICENSING BOARD DISCIPLINARY ACTIONS

Over a 22-year period, psychology licensing boards in the United States took 3,471 disciplinary actions. The major causes of the 2,858 cases for which causes were reported (with the percentage of total identified causes indicated in parentheses) were sexual or nonsexual dual relationship with a patient (30%); unprofessional, unethical, or negligent practice (29.5%); criminal conviction (9%); fraudulent acts (6%); inadequate or improper record keeping (5.5%);

noncompliance with continuing educational requirements (4.5%); breaching confidentiality (4.5%); inadequate or improper supervision (4%); psychological impairment affecting practice (4%); and fraud in applying for a license (2%).

During the same period, Canadian psychology licensing boards took 142 disciplinary actions. The major causes of the 109 cases for which causes were reported include (because the total is 109 and most categories have only between one and four cases, absolute numbers rather than percentages will be included in parentheses): unprofessional, unethical, or negligent practice (39); sexual/dual relationship with patient (35); breach of confidentiality (5); malpractice (4); conviction of crimes (4); failure to meet conditions of candidacy (3); improper termination of therapy (3); failure to adhere to standards (3); improper/inadequate record keeping (2); fraud in application for license (2); fraudulent acts (2); improper experimental treatment (2) impairment (1); failure to timely report child abuse (1); boundary violations (1); improper or inadequate supervision (1); and practice outside scope (1).

#### PROFESSIONAL LIABILITY SUITS

Multiyear statistical data on categories for professional liability suits filed against Canadian psychologists were unavailable. However, 10 years' worth of data on psychologists in the United States suggest the following areas of difficulty, based on the amount in claims paid out for such suits (with the percentage of claims paid out in parentheses): ineffective treatment/failure to consult/failure to refer (29%); failure to diagnose/improper diagnosis (16%); custody dispute (10%); sexual intimacy/sexual harassment and/or sexual misconduct (95%); breach of confidentiality (8%); suicide (4%); and supervisory issues, conflict of interest or improper multiple relationships (3%).

### Confidentiality, Privacy, and Privilege

Confidentiality allows psychotherapy patients to tell their therapists secrets they might tell no one else. Even with confidentiality, it can take great courage for some patients to mention what to them is almost impossible to speak aloud: humiliating failures, sexual longings, loss of religious faith, betrayal of a partner, hatred of a new child, shame about looks or abilities, cheating to get ahead, thoughts of killing themselves, fears and anxieties they've kept hidden from others. But without confidentiality, these patients might not speak at all.

The sensitive nature of what many patients tell clinical psychologists places a great ethical responsibility

on psychologists not to breach patients' trust, even unintentionally. An initial step is to understand three often confused terms: privacy, confidentiality, and privilege.

*Privacy* is the individual's right to decide how much personal information or private values, beliefs, preferences, or behavior should be known by anyone else, particularly government officials or agencies. In a law review article, and later in his court decisions, Louis Brandeis discussed the nature and importance of privacy. In his dissent in *Olmstead v. U.S.* (1928), he wrote:

> The makers of our Constitution undertook to secure conditions favorable to the pursuit of happiness. They recognized the significance of man's spiritual nature, of his feelings and of his intellect . . . They sought to protect Americans in their beliefs, their thoughts, their emotions, and their sensations. They conferred as against the government the right to be left alone—the most comprehensive of rights and the right most valued . . . .

The U.S. Constitution addresses basic privacy rights—such as freedom from unreasonable search and seizure—in the Fourth, Fifth, and Fourteen Amendments. The Canadian government addresses privacy rights in the Privacy Act of 1982, the Personal Information and Electronic Documents Act (PIPEDA), and Section 8 of the Canadian Charter of Rights and Freedoms (1982).

*Privilege* defines the information that is protected from disclosure in trials or other legal procedures. The courts, particularly in criminal trials where someone's liberty and sometimes life is at stake, place an almost absolute value on considering all relevant facts. However, the importance and benefits of some forms of communication—for example, between lawyers and their clients or therapists and their patients—are considered so valuable that they are protected against disclosure. The privilege virtually always belongs to the patient, rather than to the clinical psychologist, and the psychologist who is asked to reveal privileged information about a patient is generally required to claim the privilege on behalf of the patient. If, however, the client waives privilege, the psychologist can, under most circumstances, be required to testify in regard to the previously protected information.

The status of psychotherapist–client privilege differs among the states, provinces, and federal court systems. After the various appellate courts in the federal districts handed down contradictory decisions, the U.S. Supreme Court considered the issue in the form of a case posing the question: Are a client's communications to a licensed clinical social worker privileged in federal court?

In *Jaffee v. Redmond* (1996), the Court recognized the privilege. Justice Stevens provided the majority's reasoning in his opinion:

> Like the spousal and attorney client privileges, the psychotherapist patient privilege is "rooted in the imperative need for confidence and trust." . . . Treatment by a physician for physical ailments can often proceed successfully on the basis of a physical examination, objective information supplied by the patient, and the results of diagnostic tests. Effective psychotherapy, by contrast, depends upon an atmosphere of confidence and trust in which the patient is willing to make a frank and complete disclosure of facts, emotions, memories, and fears. Because of the sensitive nature of the problems for which individuals consult psychotherapists, disclosure of confidential communications made during counseling sessions may cause embarrassment or disgrace. For this reason, the mere possibility of disclosure may impede development of the confidential relationship necessary for successful treatment. (*Jaffee v. Redmond*, 1996)

Although the reasoning of the majority prevailed, it is worth noting the scathing skepticism expressed by Justice Scalia, who was joined by the Chief Justice in his dissent:

> When is it, one must wonder, that the psychotherapist came to play such an indispensable role in the maintenance of the citizenry's mental health? For most of history, men and women have worked out their difficulties by talking to, inter alios, parents, siblings, best friends and bartenders—none of whom was awarded a privilege against testifying in court. Ask the average citizen: Would your mental health be more significantly impaired by preventing you from seeing a psychotherapist, or by preventing you from getting advice from your mom? I have little doubt what the answer would be. Yet there is no mother–child privilege. (*Jaffee v. Redmond*, 1996)

*Confidentiality* refers to a clinical psychologist's duty not to reveal information about a client to anyone else unless the client provides voluntary informed consent or unless a valid legal authority allows or requires the disclosure. The nature and scope of confidentiality can be defined by legislation, by a court in the form of case law, by psychology licensing board regulations and other forms of

administrative law, and by the ethical standards of professional organizations.

Sometimes, psychologists may or must set aside confidentiality. Some common exceptions include:

• When patients provide informed consent for the psychologist to disclose confidential information to third parties (e.g., to a health insurance company covering some of the costs of therapy, to another provider of clinical services)

• When patients place their psychological state at issue before the court through filing a lawsuit or related claim. For example, a patient who has been hit by a car may develop post-traumatic stress disorder (PTSD) and sue the car's driver for damages, including the cost of therapy to address the PTSD. Filing a suit in which the patient's claim of suffering PTSD and needing treatment will be at issue can constitute a waiver of both confidentiality and privilege.

• When patients become a danger to self, a danger to others, or gravely psychologically disabled, a jurisdiction may allow or require clinicians to take steps—which can include breaching confidentiality—to protect the patient or third parties.

Such exceptions differ among the different states, provinces, and federal systems. A disclosure that is permitted in one jurisdiction may be required in another and prohibited in a third. Changes can occur within a particular jurisdiction as the legislature enacts new laws, the appellate courts recognize new duties or overturn prior requirements, and as licensing boards change their regulations. It is crucial that psychologists remain aware of the evolving requirements within the relevant jurisdictions.

Ethical missteps can occur through lack of awareness of current legal requirements in a particular jurisdiction, but can also happen when a legal analysis becomes a substitute for—rather than a supplement to—ethical analysis. In a detailed analysis, M. A. Fisher (2008) wrote that an overemphasis on legal aspects has tended to shift the focus from the therapist's concern for the client's welfare to how therapists can avoid legal problems and manage risks to themselves (instead of to their patients). Consequently, attorneys have emerged as the perceived experts on confidentiality in psychotherapy. According to Fisher, the increasing dominance of attorney-led workshops on risk-management, compliance with confidentiality requirements, and so on have replaced psychologists' own clinical and ethical language with legal terminology and drawn

psychologists' focus to avoiding "risks to themselves, when what they need is a clearer focus on their ethical obligations and the potential risks to clients" (M. A. Fisher, 2008).

The tendency of legislatures and courts to impose more exceptions to confidentiality and additional mandated reporting duties on therapists has sparked controversy among psychologists concerned with unintended consequences. Gonsiorek (2008), for example, noted that confidentiality was becoming more porous, particularly regarding mandated reporting statutes, and wrote that "as health care professionals become deputized as agents of the state—without consent, compensation, or training—for a broadening array of functions, the net effect may undermine the core of the health-care relationship" (p. 374).

In many cases, violations of confidentiality are unrelated to legal complexities and mandated exceptions but occur through the clinician's lack of attention. Here are a few sources of careless violations discussed in more detail by Pope and Vasquez (Pope & Vasquez, 2010):

• Providing confidential information to an insurance company, managed care company, or similar organization without prior informed consent

• Discussing a patient's progress in treatment with a referral source without obtaining the patient's informed consent

• Consulting a colleague about a patient without the patient's informed consent

• Consulting a colleague about a patient when others might overhear (e.g., in a hallway, elevator, cafeteria)

• Leaving charts unattended

• Unintentionally revealing confidential information when talking with the patient's family

• Unintentionally revealing confidential information when talking to one's own family or friends

• Unintentionally revealing confidential information to others in phone, fax, or e-mail messages to patients

• Failing to anticipate and address the many ways in which confidential information stored in or transmitted by computer can be compromised

## Informed Consent

Informed consent respects the autonomy of the individual patient and the patient's right to make informed choices about what psychological assessments or

treatments, if any, to receive. The right is not absolute. In emergencies and other exceptional circumstances, the right may be temporarily limited.

### A Relatively Recent Concept

The health-care professions were relatively late in recognizing the right of informed consent. The concept is nowhere to be found in the Hippocratic Oath, which assumed that the physician knew best. On what basis could patients, who lacked understanding of diagnosis and treatment, make decisions that required years of specialty education? It was only in the 20th century that this paternalistic view began to give way to recognition of the patient's right to choose, a shift prompted by the courts.

Although the case had little impact for decades, *Schloendorff v. Society of New York Hospital* (1914) clearly stated the contemporary view of informed consent as a basic right. Judge Benjamin Cordozo, later a justice of the U.S. Supreme Court, wrote that "every human being of adult years and sound mind has a right to determine what shall be done with his own body" (p. 93).

The major change in thinking about informed consent occurred after World War II, when evidence emerged of the horrors inflicted by physicians, psychologists, and others in the name of treatment or research under the Nazi regime (Cocks, 1997; Geuter, 1992; Lifton, 2000; Proctor, 1988). The Nuremberg trials—especially those in which doctors were defendants—and the Nuremberg Declaration gave the individual a basic right to veto the treatment or research plans suggested by a professional (Annas & Grodin, 1995; T. Taylor, 1993, 1997).

The increasing number of legal cases setting standards for informed consent prompted professionals to address these issues in their ethics codes. The APA devotes several sections to addressing responsibilities (3.10a, b, c, &d; 9.03a & b; 10.01a, b, & c; 10.02a; 10.03; 10.04), and Truscott and Crook (2004) note that "informed consent is the most represented value in the Canadian Code of Ethics for Psychologists" (p. 55).

### The Patient's Competence

For the process of informed consent to be meaningful, the patient must be competent to consent to or refuse treatment (Appelbaum, 2007; Berner, 1998). The psychologist must assess whether the patient can adequately:

- Understand the current situation (e.g., why treatment is indicated), the recommended treatment, the available alternatives, and the consequences of agreeing to or refusing treatment
- Engage in decision-making
- Make a choice free of coercion (i.e., the consent or refusal is voluntary)
- Communicate that choice

### Helpful Information

What information do clinical psychologists need to provide, so that patients can make informed decisions? The content will vary significantly depending on many factors, including the setting (e.g., inpatient, outpatient, day treatment), modality (e.g., individual, couple, family, or group therapy), and patient's prior knowledge and cognitive abilities. However, many patients will find clear answers to the following questions useful in making a truly informed decision:

- *Why am I here?* Many patients will have sought therapy and scheduled an initial appointment or will have been referred and understood the reason for the referral. But a surprising number may have been referred by an internist concerned about the patient's depression or impaired cognition, an attorney who wishes them to receive a psychological assessment or to be in therapy related to pending litigation, or a family member who is insistent that "you need to talk to a therapist." These patients may know that someone believes it important that they talk with you and may have even scheduled an appointment for them, but they do not understand why.
- *Who are you?* New patients may have no idea whether the person they are meeting with is a practicum student, an intern, or licensed clinical psychologist. Do you have the qualifications and experience to help them?
- *Who will be involved in the treatment?* Will the person conducting the initial interview provide the therapy, or is one purpose of the screening interview to decide which psychologist, intern, etc., within an organization is the best qualified to help this particular patient? Will the therapist be supervised?
- *What treatment is recommended, what does it involve, and what is the basis for the recommendation?* What evidence, if any, suggests that this treatment will likely be effective for this problem?
- *How much does each session cost?* Is the fee covered in whole or in part by private insurance, managed care, an employee assistance plan, or other source? Will the patient be charged for missed or cancelled appointments?

• *To what extent is what the patient tells the psychologist confidential?* What are the limits to confidentiality? Are there any circumstances that would require the psychologist to breach confidentiality? A patient who learns for the first time that a psychologist must contact authorities *after* making a disclosure in the expectation of confidentiality has not been accorded informed consent.

• *What external factors, if any, are likely to affect the therapy?* Does a managed care contract limit the number of sessions to ten in the absence of a life-threatening situation? Is the therapist scheduled to complete an internship and move on some time within the likely course of therapy, so that a new therapist will be assigned to this patient?

### Cognition, Communication, and Decision-making

Research in cognitive psychology and related areas has increased understanding of how people make decisions, and how decisions are affected by age, heuristics, and other factors (Birnbaum, 2008; Dijkstra, Jaspers, & van Zwieten, 2008; Doya, 2008; Fischhoff, 2008; Gatz, 2006; Gilovich, Griffin, & Kahneman, 2002; Reyna & Rivers, 2008; Sinz, Zamarian, Benke, Wenning, & Delazer, 2008; Tversky & Kahneman, 2004, 2005; Williams-Piehota, McCormack, Treiman, & Bann, 2008; Zikmund-Fisher, Lacey, & Fagerlin, 2008). Staying abreast of this research enables psychologists to present information in ways that are best suited to the cognitive capacities and styles of the individual patient and that take into account the nature of the relevant information that the patient needs to make an adequately informed decision.

Presenting the same basic information but in a different format can profoundly affect the patient's decision-making process. A classic study at a Harvard Medical School hospital provides an example. McNeil and her colleagues (McNeil, Pauker, Sox, & Tversky, 1982) presented people with a choice of two possible treatments. The information she provided to help them make a decision was actuarial data of previous outcomes. Patients with lung cancer had chosen either surgery or radiation. When the patients had chosen surgery, 10% had died during the surgery, and another 22% died less than a year after the operation. Thirty-four percent died between 1 year and 5 years after surgery. None of the lung cancer patients who had decided to undergo radiation therapy died during the radiation sessions, but 23% died less than a year later, and 55% died between 1 and 5 years after the radiation sessions.

These actuarial data were presented in the form of mortality: how many patients died at each stage. Presented with these mortality statistics, well over a third of the study participants (42%) reported that they would choose radiation therapy. However, when the same actuarial data were presented in the form of survivability (e.g., of those who chose radiation treatment, 100% survived the radiation treatments, 77% survived at least a year, and 22% survived at least 5 years), the percentage of participants who chose radiation treatment dropped to 25%. Whether the same actuarial statistics were presented in terms of mortality or survival significantly affected the decision-making process.

The decisions patients make—for example, whether to begin psychotherapy and if so, what kind; whether to take psychotropic medications; or whether to voluntarily begin inpatient treatment—can have profound and lasting effects for themselves and for others. To make adequately informed decisions to consent to or refuse treatment, they need to understand the relevant information. Maintaining awareness of the evolving research on how people receive and process information in arriving at decisions helps psychologists to provide the relevant information in a clear, fair, and helpful way.

### Forms

Forms for informed consent can serve an important purpose. Their precise wording can avoid the misstatements of oral presentations. Both patient and therapist can save a copy, so that neither will have to trust to the potential glitches of memory regarding what, exactly, was consented to.

But forms also can tempt therapists to believe a comforting fallacy: that words on paper can handle the complex ethical responsibility of making sure that the patient understands the information and is giving consent both knowingly and voluntarily. Even when forms are used, psychologists must discuss the information with the client, assessing the patient's understanding.

Psychologists must also assess the forms. Are they readable? Grundner (1980) observed long ago that great attention is paid to making sure that all the right content goes into consent forms but relatively little effort is made to see whether people can understand the forms. He used standardized readability assessment instruments to study five consent forms. He reported that all required the reading abilities of advanced undergraduates or graduate students, and that all but one were "written at the level of a scientific journal, and the fifth at the level of a specialized

academic magazine" (p. 900). Unfortunately, readability is still a hurdle for many patients, although research is increasing our understanding of readability issues and how forms can be improved (Aleligay, Worrall, & Rose, 2008; Christopher, Foti, Roy-Bujnowski, & Appelbaum, 2007; Collins, Novotny, & Light, 2006; Hochauser, 1997; Martin, 2005; Paasche-Orlow, H. A. Taylor, & Brancati, 2003; Walfish & Ducey, 2007; Wallace et al., 2008).

Some patients, of course, may not be able to read even the most seemingly readable form. It is important for psychologists to know if the patient can read and whether English (or whatever language the form is written in) is appropriate for the patient.

Many forms—especially those for clinics, hospitals, and similar organizations—will be carefully reviewed by an attorney, a risk-management specialist, an administrator, and other nonpsychologists. This is good practice to make sure that the form meets legal and administrative standards. However, there is some risk that when the review process exclusively focuses on legal and administrative needs, the legitimate needs of patients may be overlooked. Akkad and her colleagues' study of patient perceptions of consent forms found that many did not perceive the purpose of the forms to be protecting their interests or finding out what interventions they wanted but, consistent with prior studies, "many thought the primary function of the form was to protect the hospital" (2006, p. 529). One way to help make sure that the primary focus of a consent form is the legitimate rights and needs of patients is to ask a few friends—particularly those who are not psychologists—to take a look at the form and critique it. If they were a patient, would they feel that the form speaks clearly to their legitimate rights and needs? Is anything missing? How would they improve it? Another way is to use the Golden Rule when reviewing the form: If you yourself went to another clinical psychologist for assessment or therapy and were handed this form, what would your reaction be?

Links to sample forms for informed consent from diverse sources including the APA Insurance Trust; excerpts addressing informed consent from the standards and guidelines (with links to the original documents) of 18 professional associations including the APA, the CPA, European Federation of Psychologists' Associations, and the Psychological Society of Ireland; and quotes about informed consent from diverse articles, books, and studies are available online at http://kspope.com/consent/index.php.

## Beyond Forms: Informed Consent as a Continuing Process

The focus on forms as an important key to obtaining informed consent can mislead us into thinking of obtaining consent as a one-time event—the signing of a form—that occurs at the beginning of therapy. It is as if, once we have the signed form, we can check "informed consent" off our mental checklist of responsibilities. But truly informed consent is a process of both patient and therapist coming to agree on a shared venture. The CPA's "Code of Ethics for Psychologists" emphasizes that psychologists "[r]ecognize that informed consent is the result of a process of reaching an agreement to work collaboratively, rather than of simply having a consent form signed" (CPA, 2000).

O'Neil discusses this process as *negotiation* in his book *Negotiating Consent in Psychotherapy*. He emphasizes the potential benefits to therapists—such as clearing up the misconceptions about a patient—as well as to patients. "An open dialogue can make the therapist aware of features of the case that depart from both the therapist's model and his or her previous experience, and thus it serves as a corrective to the representativeness and availability biases" (O'Neill, 1998, p. 176).

Finally, the process can continue throughout the course of therapy. The patient's condition can change significantly (if not, perhaps the treatment plan needs rethinking) or events in the patient's life may shift the focus away from the original presenting problem(s). These and other factors may prompt therapist and patient to renegotiate their original agreement, and the patient may provide or withhold informed consent for the new possibilities.

## Competence

An ethic of competence is a cornerstone for any profession. How many readers would consider entrusting themselves or their loved ones to an incompetent surgeon, attorney, or psychotherapist?

### Ethics Codes

The ethics codes emphasize competence as a fundamental ethical responsibility. Ethical Standard 2.01a of APA's "Ethical Principles of Psychologists and Code of Conduct" states: "Psychologists provide services, teach, and conduct research with populations and only within the boundaries of their competence, based on their education, training, supervised experience, or appropriate professional experience" (APA, 2002, p. 1063). Ethical Standard II.6 of the "Canadian Code of Ethics for Psychologists" states

that, in adhering to the Principle of Responsible Caring, psychologists perform without supervision any activity only if "they have established their competence to [perform that activity] to the benefit of others" (CPA, 2000).

### *Learning Competence*

Graduate school, practica, and internship help us acquire basic competence in clinical psychology. We learn about theory, research, and practice, and how to apply critical thinking skills to evaluate them. We learn, under careful supervision, how to conduct assessments and a range of psychological treatments (Barlow, 2004). We learn to evaluate our work and its consequences, to seek and consider feedback from others. We develop sound professional judgment.

Training in clinical psychology also involves acquiring what Pope and Brown termed *emotional competence for therapy* (Pope & Brown, 1996; Pope, Sonne, & Greene, 2006; Pope & Vasquez, 2010). Emotional competence is in part an active awareness of the emotional aspects of providing clinical services, the ways in which the work can be stressful, and the need to recognize when we have reached, however briefly, the limits of our emotional competence. Pope and Vasquez (2010), for example, reviewed national surveys of psychologists in which:

• Over half of the respondents reported crying in the presence of a patient
• Almost a third reported hating a patient
• Almost one-fifth reported having been physically attacked by a patient
• Almost four-fifths reported having been afraid that a client would attack them
• About one-fourth reported having summoned police or security personnel to protect them from a patient
• Almost all reported being afraid that a patient would commit suicide
• Over half reported becoming sexually aroused in the presence of a patient
• About nine-tenths reported feeling fear because a patient's condition became suddenly or seriously worse
• Almost nine-tenths reported having felt afraid that a colleague would be critical of their work
• About two-thirds reported feeling afraid that a patient would file a formal complaint against them

Some areas of practice may tend to involve more intense emotional reactions. Pope and Garcia-Peltoniemi (1991), for example, described the emotional responses experienced by many who provide psychological treatments to victims of torture.

Formal training fosters a growing awareness that competence must be evaluated for each situation. A psychologist who is exceptionally skilled at working, for example, with adults, with people suffering from schizophrenia, with individual psychotherapy, or with airline pilots might lack basic competence in working with children, with people suffering from performance anxiety, with group therapy, or with war refugees. These limitations on the generalization of competence can pose difficult challenges for clinical psychologists in small communities, when the closest professional with the necessary competence for a specific patient may be many hours away. Psychologists facing those dilemmas often have no alternative if the patient's needs are urgent than to undertake the psychological treatment, if possible, while obtaining long-distance supervision from a qualified professional.

### *Competence and Methods of Assessment and Intervention*

Psychologists must evaluate not only their own competence but also the competence of the methods that they use. Although difficult challenges remain, the field has made great progress in this area. As recently as the landmark Boulder Conference, psychology was still struggling just to define what psychotherapy was, so that graduate schools could teach it effectively. APA president Carl Rogers created a committee, chaired by David Shakow, to report on what psychotherapy was and what training students needed in order to achieve competence. The 1947 APA convention adopted the Shakow report, which laid the ground work for the Boulder Conference in 1949. George Lehner, the recorder for the Boulder Conference task force charged with providing a formal definition for psychotherapy and specific recommendations for the training to ensure competence, offered this summary of their work: "We have left therapy as an undefined technique which is applied to unspecified problems with a nonpredictable outcome. For this technique we recommend rigorous training" (1952, p. 547).

Just as the APA returned to its scientific and empirical roots to construct a unique ethics code based on the experience of its members, psychology returned to those same roots to address questions of competence related to psychotherapy and other psychological treatments. The field began to focus on research that explored the effects caused by various interventions with various populations under

various conditions. Singer's (1980) classic article, "The Scientific Basis of Psychotherapeutic Practice: A Question of Values and Ethics," exemplified the growing recognition that psychologists had ethical as well as practical reasons for staying abreast of the empirical basis of their methods of psychological assessment and treatment. Ethically, it was hard to justify ignoring evidence that some techniques were less effective than others under the same circumstances, and that some could cause harm. Stricker emphasized this ethical responsibility: "[A]lthough it may not be unethical to practice in the absence of knowledge, it is unethical to practice in the face of knowledge . . . . [T]here is no excuse for ignoring contradictory data" (1992, p. 564). Barlow noted how research has challenged conventional wisdom and practices, and brought sweeping changes in the field. "Stunning developments in health care have occurred during the last several years. Widely accepted health-care strategies have been brought into question by research evidence as not only lacking benefit but also, perhaps, as inducing harm" (Barlow, 2004, 2005a, 2005b; Huppert, Fabbro, & Barlow, 2006).

The strengths of empiricism have enabled psychology to progress in identifying aspects of competence and how they can be learned with greater precision than was possible at the Boulder Conference. For example, the *Mutual Recognition Agreement of the Regulatory Bodies for Professional Psychologists in Canada* (2004) focused on five core aspects of competence:

- Assessment and evaluation
- Ethics and standards
- Interpersonal relationships
- Intervention and consultation
- Research

The *2002 Competencies Conference: Future Directions in Education and Credentialing in Professional Psychology* (Kaslow, 2004; Kaslow et al., 2004) focused on how to assess and teach eight domains of core competence:

- Consultation and interprofessional collaboration
- Ethical and legal issues
- Individual and cultural diversity
- Intervention
- Professional development
- Psychological assessment
- Scientifically minded practice
- Supervision

The *Competencies Conference* led to the APA Task Force on Assessment of Competence in Professional Psychology and other advancements in defining, assessing, and teaching competence (Kaslow, Rubin, Bebeau, et al., 2007; Kaslow, Rubin, Forrest, et al., 2007).

Challenges persist in the midst of this substantial progress. Kazdin (2006), for example, noted that "[p]sychotherapy outcome research has been dominated by randomized controlled trials . . . . However, pivotal features of these trials make them not very relevant for clinical practice" (see also Goodheart, 2006; Sternberg, 2006). He also observed that the number of psychological treatments continues to grow rapidly—over 550 in his specialty of child and adolescent therapy—and that only a small minority of them had been studied in any kind of research trials (Kazdin, 2008).

When focusing on the progress and remaining challenges of a clinical psychology that is informed by research, it is important to remain aware that an evidence-based practice does *not* mean that professional judgment and experience are set aside in order to reflexively apply research findings, as if that were possible. Professional expertise is essential. The APA Presidential Task Force on Evidence-Based Practice underscored "the need to integrate clinical expertise with the best available research" (APA Presidential Task Force on Evidence-Based Practice, 2006, p. 282).

## Boundaries

Handled with appropriate professional judgment and care, nonsexual boundary crossings can play a positive—sometimes seemingly key—role in psychological treatment. However, they also have the potential to sabotage the treatment plan and harm the client.

Consider these hypothetical scenarios:

- "My attorney is depressed, wants to start therapy, and says I am the only one she would trust with her problems—should I accept her as a patient?"
- "One day a week the last patient of the day needs a ride home—is there any reason I shouldn't provide it?"
- "A patient is about to lose his house because he is short on his mortgage payment and has been unable to secure a loan—I can easily afford to lend him the money and would like to, but am uncertain if I should."
- "A client has invited me to replace the pianist who has just left his jazz trio that plays weekends at

a local nightclub—this is a once-in-a-lifetime opportunity for me but I wonder if I should accept."

• "My infant son needs life-saving surgery that I can't afford and the only way to pay for it is to ask a wealthy patient who is always telling me how much therapy is helping her and that I should just ask if I even need anything. Is it OK to ask her to for a loan? What if the reason I need the money is for a Paris vacation because I am totally burnt out, have never been to Paris, and am sure I would return refreshed and a better therapist?"

Situations like these ignited one of the most vigorous controversies in clinical psychology, reaching its peak in the period from the beginnings of the 1980s to the mid-1990s, and continuing to challenge the field today. In the 15 years beginning in 1980, a wealth of individual journal articles and journal special issues challenged or endorsed virtually every possible prohibition involving different nonsexual boundaries (Pope & Keith-Spiegel, 2008; Pope & Vasquez, 2010). Thoughtful articles examined the issues in light of diverse perspectives, values, and theoretical orientations. Research during that period explored the ways in which therapists' beliefs and behavior in regard to nonsexual boundaries were significantly associated with such factors as therapist gender, patient gender, size of the local community, profession, practice setting (e.g., hospital vs. solo practice), and theoretical orientation.

Much of the discussion focused on how the ethics code section addressing nonsexual boundary issues might be changed. For example, on the basis of their replication of the critical incident study that formed the basis of the original APA ethics code, Pope and Vetter (1992) recommended that the current APA ethics code be changed to

• Provide a more precise definition of dual relationships and specify when they might be appropriate
• Take account of the realities of psychological practice in geographically isolated areas, small communities, etc.
• Clarify the differences between dual relationships that the psychologist enters into by choice and those which are unavoidable or occur by chance

Two factors may have made it harder to address nonsexual boundary issues realistically. First, the discomfort with sexual boundary issues that many therapists experienced may have generalized into a discomfort with nonsexual boundary issues as well. The prohibition against violating sexual boundaries with patients dates back to the Hippocratic Oath and even to the more ancient Code of the Nigerian Healing Arts. That prohibition, as pertains specifically to psychotherapy, dates back to Freud. As the judge in a widely cited mid-1970s case wrote: "Thus from [Freud] to the modern practitioner we have common agreement of the harmful effects of sensual intimacies between patient and therapist" (*Roy v. Hartogs*, 1976). Nevertheless, surveys of therapists in different disciplines found that a majority of respondents reported that simply experiencing sexual attraction to a patient made the therapists feel anxious, guilty, or confused (Pope, Sonne, & Holroyd, 1993; see also Pope et al., 2006).

Second, the concept of clear, helpful, ethical boundaries may have become confused with the concept of inflexible boundaries. Some of the discussion seemed to have an all-or-none absolutist quality. Either a particular boundary—such as nonsexual touch, dual roles, or out-of-the-office meetings with patients—should be completely prohibited, or it was always acceptable.

A landmark article, "The Concept of Boundaries in Clinical Practice" (Gutheil & Gabbard, 1993) helped transform this area, providing a practical framework for clinicians to use in considering boundary decisions. After observing that many of those who endorsed inflexible boundaries cited Freud as a model and influence, the authors pointed out that Freud loaned books to his patients, gave gifts to them, told them about his family, shared a walk with a patient through the countryside during a treatment session, met a patient for a meal while he was on vacation, and conduced a psychoanalysis of Anna, his daughter.

Gutheil and Gabbard avoided an absolutist approach to any nonsexual boundary decision, arguing that any decision must be based on a case-by-case analysis of the specific facts and clinical context. Their framework identified the concepts of *boundary crossing* and *boundary violation*. A boundary crossing is a neutral descriptive term to indicate an instance when a therapist decides not to observe a particular boundary. A boundary crossing can be therapeutic, can harm the patient, or can produce no significant impact, depending on the specific situation and clinical context. Boundary crossings that were harmful were termed boundary violations. The article provided examples of therapeutic or acceptable boundary crossings, and of boundary violations involving boundaries of role, time, place

and space, money, gifts, services, clothing, language, self-disclosure, and physical contact.

A subsequent article, which had a similar influence on the field, examined how the concept of boundaries was sometimes misunderstood and misused by licensing boards and others who enforce formal policies (Gutheil & Gabbard, 1998).

These and similar articles tended to shift the focus in this area away from general rules that approved or prohibited large classes of nonsexual boundary crossings toward sets of useful steps clinicians could take in thinking through whether to cross a specific boundary with a specific client in a specific situation. Here are a variety of decision-making guides for nonsexual boundary issues, some of which are available on the web:

• "A guide to violating an injunction in psychotherapy: On seeing acquaintances as patients" (Roll & Millen, 1981)—a nine-step model
• "Avoiding exploitive dual relationships: A decision-making model" (Gottlieb, 1993) a five-step model
• "Managing multiple relationships in rural communities" (Faulkner & Faulkner, 1997) multilevel guidelines
• "Sexual and nonsexual boundary violations involving psychologists, clients, supervisees, and students: Implications for professional practice" (Lamb & Catanzaro 1998—a six-step model
• "Ethical decision-making and dual relationships" (Younggren, 2002)—an eight-step model
• "Acknowledging the inevitable: Understanding multiple relationships in rural practice" (Campbell & Gordon, 2003)—a five-step model
• "Addressing multiple relationships between clients and therapists in lesbian, gay, bisexual, and transgender communities" (Kessler & Waehler, 2005)—a six-step model
• "Nonsexual multiple relationships: A practical decision-making model for clinicians" (Sonne, 2005)—a multilevel approach
• "A practical approach to boundaries in psychotherapy: Making decisions, bypassing blunders, and mending fences" (Pope & Keith-Spiegel, 2008)—a nine-step model

Additional resources for considering boundary decisions are available at http://kspope.com/dual/index.php. These include excerpts on boundaries from the ethics codes of 29 professional associations (e.g., APA, CPA, Australian Psychological Society,

Psychological Society of Ireland, European Federation of Psychologists' Associations, British Association for Counselling & Psychotherapy) with links to the complete codes, excerpts from books and articles addressing boundary issues, and links to articles on boundaries.

## An Area of Major Controversy: Clinical Psychology and National Security

Psychology's involvement in national security efforts following the terrorist attack on the United States on September 11, 2001 sparked major controversy and raised complex ethical questions. As the scenario about Homeland Security officials asking a clinical psychologist for a patient's records at the start of this chapter illustrated, one set of questions asks under what circumstances and to what extent should therapy patients' records be made available to third parties if they might lead to information about terrorist attacks or serve other national security purposes? Should therapy and other clinical records be made available to those conducting detainee interrogations? Should therapy or other clinical services be used as a pretext to gain information related to national security? Should psychologists help plan or implement the interrogation of individual detainees?

The APA's approach to detainee interrogations, which was based on the work of the Presidential Task Force on Psychological Ethics and National Security (APA, 2005), emphasized that psychologists' rightly assumed a key role in interrogations in part because interrogations were an inherently psychological process requiring psychological expertise. The "Statement of the American Psychological Association on Psychology and Interrogations Submitted to the United States Senate Select Committee on Intelligence" emphasized:

> Conducting an interrogation is inherently a psychological endeavor . . . . Psychology is central to this process because an understanding of an individual's belief systems, desires, motivations, culture, and religion likely will be essential in assessing how best to form a connection and facilitate educing accurate, reliable, and actionable intelligence. Psychologists have expertise in human behavior, motivations, and relationships . . . . Psychologists have valuable contributions to make toward . . . protecting our nation's security through interrogation processes.
> (APA, 2007)

This special expertise set psychologists apart from psychiatrists and other physicians, who lacked

competence in this area, according to the APA. The Director of the APA Ethics Office wrote: "This difference, which stems from psychologists' unique competencies, represents an important distinction between what role psychologists and physicians may take in interrogations" (Behnke, 2006, p. 6).

The contrast with physicians was striking, though physician associations stated that the difference was not one of competence but of ethics. The American Medical Association prohibited participation in detainee interrogations to such a degree that they banned even monitoring an interrogation with an intent to intervene (Moran, 2006; Ray, 2006). Commenting on the American Psychiatric Association's prohibition (American Psychiatric Association, 2006), the American Psychiatric Association president Steven Sharfstein (2006) wrote: "I told the generals that psychiatrists will not participate in the interrogation of persons held in custody. Psychologists, by contrast, had issued a position statement allowing consultations in interrogations. If you were ever wondering what makes us different from psychologists, here it is. This is a paramount challenge to our ethics and our Hippocratic training … . Our profession is lost if we play any role … ." (p. 1713).

The difference in ethical policies among the professions led to differences in involvement. As the *New York Times* reported:

> Pentagon officials said Tuesday they would try to use only psychologists, not psychiatrists, to help interrogators devise strategies to get information from detainees at places like Guantánamo Bay, Cuba. The new policy follows by little more than 2 weeks an overwhelming vote by the American Psychiatric Association discouraging its members from participating in those efforts. Stephen Behnke, director of ethics for the counterpart group for psychologists, the American Psychological Association, said psychologists knew not to participate in activities that harmed detainees. But he also said the group believed that helping military interrogators made a valuable contribution . . . .
> (Lewis, 2006; see also Hausman, 2006)

The APA provided a compelling rationale for psychologists' involvement in detainee interrogations, emphasizing important benefits such as psychologists' "valuable contributions" toward "protecting our nation's security through interrogation processes" and their inherent knowing "not to participate in activities that harmed detainees." The 2007 president of the APA wrote: "The Association's position is rooted in our belief that having psychologists consult with interrogation teams makes an important contribution toward keeping interrogations safe and ethical."

Nevertheless, psychologists' involvement was controversial. Eban (2007; see also Goodman, 2007) was among those who documented ways in which "psychologists weren't merely complicit in America's aggressive new interrogation regime. Psychologists, working in secrecy, had actually designed the tactics and trained interrogators in them … . " Having published a series of investigative reports on the nature of psychologists' involvement in interrogations, the *Boston Globe* (2008) stated: "From the moment U.S. military and civilian officials began detaining and interrogating Guantanamo Bay prisoners with methods that the Red Cross has called tantamount to torture, they have had the assistance of psychologists … . " In April 2009, an American Civil Liberties Union (ACLU) Freedom of Information request led the U.S. Justice Department to release documents previously classified as top secret. These documents revealed the significant number and wide range of psychologists involved directly or indirectly with what had come to be called extreme interrogations. For example, they noted the roles played not only by "on-site psychologists" but also by "outside psychologists" in justifying the use of waterboarding and other techniques. (American Civil Liberties Union, 2009). The prominence of this ethical controversy was exemplified by the cover of the May 16, 2009 *British Medical Journal* (vol. 338, No. 7704), which showed an photograph from Abu Ghraib and the words: "Interrogating Detainees: Why Psychologists Participate and Doctors Don't."

It is important to note that some physicians were also involved in detainee interrogations (Lifton & Xenakis, 2006). However, physicians who conducted, directly participated in, or monitored an interrogation with an intent to intervene did so *despite* the American Medical Association's and the American Psychiatric Association's explicit ethical prohibition and formal statements condemning such involvement. In contrast, the APA's public statements emphasized that psychologists (unlike physicians) were uniquely qualified, that interrogations were inherently a psychological process, that psychologists "knew not to participate in activities that harmed detainees," and that psychologists were making important contributions to national security and to keeping the interrogations safe and ethical. Commenting on the striking differences between APA and the medical professional associations,

Professor of Medicine and Bioethics Steven Miles, author of *Oath Betrayed: America's Torture Doctors*, wrote: "The American Psychological Association was unique among US health professional associations in providing policy cover for abusive interrogations…" (2009). Amnesty International, Physicians for Human Rights, and 11 other organizations sent an open letter to APA ("Open letter," 2009) about what it termed APA's "grievous mismanagement of this issue"; APA's "providing ethical cover for psychologists' participation in detainee abuse"; and APA's handling of the detainee interrogation issue creating "the greatest ethical crisis" in the profession's history and making a "terrible stain on the reputation of American psychology."

The controversy over complex questions about the relationship of ethics to national security—Is it ethical for the clinical psychologist in the scenario at the beginning of this chapter to hand over the client's records to Homeland Security and help them design an interrogation? Is it ethical for the psychologist to refuse in light of the massive loss of lives that might occur as a result of refusing?—was heightened by a change in ethical policy regarding the relationship of ethical responsibilities to the authority of the state.

The ethics code had stated that psychologists' ethical responsibilities might conflict with governmental authority. In the year following the terrorist attacks of September 2001, however, the APA added a new statement to Section 1.02 of the code's enforceable ethical standards: "If psychologists' ethical responsibilities conflict with law, regulations, or other governing legal authority, psychologists make known their commitment to the Ethics Code and take steps to resolve the conflict" (APA, 1992, p. 1600). The editor of the *British Medical Journal* was among those who criticized this abandonment of the Nuremberg ethic:

> Just obeying the rules has long been insufficient for doctors. The judges at Nuremberg made clear that obeying commands from superiors didn't remove personal accountability. Doctors couldn't deviate from their ethical obligations even if a country's laws allowed or demanded otherwise. The World Medical Association is meeting as I write. Its most noteworthy contribution has been the drafting of the Helsinki Declaration on Ethical Principles for Medical Research Involving Human Subjects. Both this and the World Medical Association's International Code of Ethics contain the crucial statement that a doctor's or investigator's conscience and duty of care must

transcend national laws. So deeply ingrained is this ethic in health care that it's surprising, even shocking, to find that the same code isn't shared by psychologists, at least in the United States.
(*Godlee*, 2009)

Writing in the British Psychological Society's *The Psychologist*, Burton and Kagan wrote that "the APA allows its members the 'Nuremberg defence' that 'I was only following orders'…. The implication is that psychologists are permitted to assist in torture and abuse if they can claim that they first tried to resolve the conflict between their ethical responsibility and the law, regulations or government legal authority. Otherwise they can invoke the Nuremberg defence…" (p. 485).

It is impossible to overemphasize the deep and daunting complexity of these issues, for which there are no simple answers. Thinking them through requires careful review of the available documents (not just the few brief excerpts quoted here), openness to the arguments and evidence on each side, willingness to respect and consider contrary views, and the weighing of conflicting values, needs, and responsibilities. Some works presenting basic data, documentation, reviews, and analysis include those by the APA (2005, 2007), Eidelson, (2009), Hutson (2006), Koocher (2006), Levine (2007), Lifton (2008), Olson and Miles (2009), Pope & Gutheil (2009a, 2009b), and Soldz (2009). A comprehensive online archive of over 360 citations of articles, chapters, and books representing the full range of views of the controversy over psychologists, psychiatrists, and other health-care professionals participating in the planning or implementation of detainee interrogations is available at http://kspope.com/interrogation/index.php.

## Steps in Ethical Decision-making

This chapter has emphasized an approach to ethical issues that is active and creative rather than passive rule-following, reflexive application of a code, or looking for a one-size-fits-all "answer" from an authority. This final section suggests a set of steps that may be helpful in thinking through situations, problems, or issues.

Such steps have always been a focus of the CPA ethics code. The original CPA code included seven steps (CPA, 1986), and the revisions have included ten steps (CPA, 1991, 2000). Fisher (C. B. Fisher, 2003), Haas and Malouf (2005), Koocher and Keith-Spiegel (2008), and Welfel (2005) are among those who have published thoughtful sets of steps

in ethical decision-making for psychologists. (See Cottone & Claus, 2000, for a review of other decision-making guides.) These guides tend to be consistent with one another, but with varied structures, perspectives, and emphases.

The following set of steps is adapted from Pope and Vasquez (2010). Some steps may not be relevant to a particular situation, problem, or issue, or may need to be adapted.

1. *Defining the problem.* What exactly is the problem, situation, or issue that serves as the focus of ethical decision-making? Can it be stated clearly and directly without euphemisms, jargon, or bias?

2. *Recognizing those whom your actions will affect.* Most of our ethical decisions affect more than one person. A client may begin to show signs of cognitive impairment that would likely affect driving skills and yet refuse to discuss finding other ways to get around. A managed care administrator may refuse to approve clinical services that seem essential for a patient with extremely violent tendencies. A colleague may show signs of abusing alcohol in a way that interferes with professional functioning. The buildings or services at a clinic may be inaccessible to those with certain physical disabilities. A fellow graduate student, intern, or licensed psychologist may be encountering discrimination based on race, religion, gender, age, sexual orientation, physical disability, or other factors. What we choose to do or avoid doing in such situations may affect many people.

3. *Identifying the client.* If the situation involves a psychologist–client relationship, is it clear who the client is? Are there any actual or potential conflicts of interest that might affect our responsibilities to our client? For example, if a managed care company or family member is paying the fee for psychological treatment, how, if at all, might that affect our work? If a company facing large damage claims from a class action suit alleging harm from a product offers us over half a million—along with hints of future assignments should they like our work—to evaluate the plaintiffs and then testify whether each has suffered psychological harm because of the company's product, would our assessment and testimony be free of bias?

4. *Assessing competence.* What kinds of competence are needed to addresses this situation, problem, or issue, and are they present? Are there practical ways in which we could improve our ability to be effective?

5. *Reviewing formal ethical standards.* Does the ethics code provide guidance in this matter? Does it speak clearly to the situation, problem, or issue? Does the matter at hand involve conflicting values within the code or conflicts between the guidance offered by the code and other sources of responsibilities, such as legal mandates or licensing board regulations? Does the ethics code's guidance seem appropriate or inappropriate in this instance?

6. *Reviewing legal requirements.* Do legislation and case law provide guidance in this matter? Do they speak clearly to the situation, problem, or issue? Do the legal requirements seem to support or permit the most ethical decision and action in this instance?

7. *Reviewing relevant research and theory.* What research and theory are relevant and helpful to the decision-making process? Are there new findings and ideas in that literature since the last time we took a look? Is there relevant work outside our own theoretical orientation and specialties that might have escaped our notice?

8. *Considering personal reactions.* Does the situation, problem, or issue evoke personal feeling that might cloud or complicate the process of ethical decision-making? Does the matter make us uncomfortable in some way? Are we concerned about pleasing, offending, angering, disappointing, or alienating someone? Are we worried because the most ethical response places at risk our income, professional advancement, popularity, job recommendations, psychology license, or safety? These are normal—and *very* common—human reactions and tend to cause problems only when they aren't honestly and openly acknowledged.

9. *Considering cultural, religious, and spiritual factors.* In what ways could cultural, religious, or spiritual factors affect our understanding of the matter at hand or the possible options? Could these factors be the cause of conflicts or miscommunications? What is viewed as ethical, appropriate, and helpful in one society or tradition may be viewed as misguided, offensive, and damaging in another context. It is important to remain aware of not only how these factors affect our clients but also of how our own cultural, religious, or spiritual contexts affect us. *The Spirit Catches You and You Fall Down: A Hmong Child, Her American Doctors, and the Collision of Two Cultures* (Fadiman, 1998) discussed the tragic consequences of failing to take such contexts into account when a California hospital and Laotian refugee family tried help to a Hmong child

diagnosed with epilepsy. Medical anthropologist Arthur Kleinman described how those involved failed to take adequate account not only the Hmong culture but also of the culture of biomedicine. He wrote: "If you can't see that your own culture has its own set of interests… and biases, how can you expect to deal successfully with someone else's culture?" (p. 261). Comas-Diaz (2006), Hansen, Randazzo, Schwartz, and colleagues (2006); Derald Wing Sue and David Sue (Sue & Sue, 2007); Stanley Sue, Zane, Levant, and colleagues (S. Sue et al., 2006); and Vasquez (2007) provide valuable resources in this area.

10. *Considering consultation.* Other perspectives and second (and third) opinions can be invaluable. Are there those with more knowledge or experience in the relevant areas? Sometimes the following hypothetical is helpful: If you imagine the worst possible case scenario resulting from an ethical decision you make regarding this situation, problem, or issue, who would you wish you'd consulted before taking action?

11. *Searching for possible responses.* Are there alternative methods of problem-solving or courses of action that have been overlooked? Often, when beginning to think through a situation, problem, or issue, a few obvious possibilities will present themselves, and these may seem adequate or perhaps appear to be the only possibilities that exist. More persistent searching for creative alternatives, rather than settling for the first arrivals, can result in better ethical decision-making.

12. *Evaluating the alternatives.* What is the most likely outcome of the various alternatives for those who will be affected? What is the best possible outcome and what is the worst possible case scenario? What are the risks, costs, and the benefits? When our actions affect others in significant ways, often the short- and long-term outcomes include unintended consequences—what could those unintended consequences be in this instance?

13. *Adopting the perspective of others.* It is worth trying to imagine what those who will be affected by our actions would view as the most ethical response to a challenging situation. This approach may broaden, deepen, and in some instances significantly change our understanding. It may also correct the distortions that viewing a situation, problem, or issue from a single limited perspective can cause. One form of this distortion is what Jones (1979; see also Blanchard-Fields, Chen,

Horhota, & Wang, 2007; Gawronski, 2003) identified as "correspondence bias": We tend to attribute our own behavior in a particular instance to situational factors while attributing the behavior of others to internal dispositions. In his classic essay "Why I Do Not Attend Case Conferences," Meehl (1989) identified another form of this distortion as the "double-standard of morals" (p. 232): We tend to subject the explanations of others to skeptical and rigorous scientific scrutiny that we avoid applying to our own explanations.

14. *Deciding on a course of action and then reconsidering it.* If time allows, it can be useful once an initial decision is made to second-guess it. Once other alternatives are eliminated, sometimes previously unnoticed flaws, costs, consequences, or implications will become evident.

15. *Taking action and assuming personal responsibility for our choices and behavior.* For some situations, problems, or issues, weighing options and making a decision are the real challenge. Having reached a decision, taking action is relatively easy. The reverse can also occur: Identifying the most ethical response is easy, but convincing ourselves to follow that path can be almost impossible. (And sometimes we simply cannot bring ourselves to "do the right thing.") When we avoid what we know or suspect is the most ethical response, it is a normal human reaction for any of us to be tempted to blur, shift, deny, or otherwise escape responsibility for our decisions and acts.

16. *Assessing the consequences.* What were the results of our actions? Did they achieve what we'd hoped? Were there unexpected consequences? How did these actions affect the clinical needs of the patient? Does the treatment plan need to be changed in any way? With the benefit of hindsight, would we do the same thing again, or would we decide on a different response?

17. *Assuming personal responsibility for mistakes.* If it becomes apparent that, despite the best of intentions, we have made the wrong decision or made mistakes in implementing what we still believe was the right decision, what steps, if any, do we need to take in assuming personal responsibility?

18. *Learning from the experience.* What can we learn from this experience that will enable us to improve our work in the future? What practical steps might be helpful? Do we need to make any changes in our policies, procedures, or the ways in which we approach certain situations?

## Conclusion
### Future Directions
- What research would provide the most accurate understanding of how clinical psychologists make ethical decisions in the context of providing psychological treatment (rather than confronting fictional scenarios representing hypothetical situations)?
- What research would provide the most useful guidance in developing ethics codes that are realistic (i.e., reflect the realities of clinical work), helpful, and based on the values of those who will be using the code?
- What research would best identify the personal and situational factors associated with clinical psychologists intentionally or unintentionally violating an ethics code?
- What research would provide the most valid assessment of the degree to which the steps that a professional association, graduate training program, internship, clinic, or other agency takes to identify and support ethical behavior are effective, irrelevant, or counterproductive?

# Creating Public Health Policy: The Dissemination of Evidenced-based Psychological Interventions

Bruce F. Chorpita, Jeanne Miranda, *and* Adam Bernstein

## Abstract

In recent years, clinical psychology has made significant contributions to mental health policy through its increasing focus on the notion of evidence-based practice and an empirical approach to clinical decision-making. These developments have not been without challenges, however. Most notable are issues with the acceptability of treatment design among practitioners and the difficulty of implementing and sustaining high-quality practices in real-world contexts. Two specific barriers central to these challenges are discussed, namely, the highly specialized architecture of most research-based mental health treatments and the unavailability of a dedicated supervisory and training infrastructure. Solutions are proposed that suggest the need to rethink both the way treatments are packaged and the way they are supported in real-world practice.

**Key Words:** Clinical psychology, evidence-based practice, mental health, mental health policy, public health policy

## Historical Background

Some of the earliest mental health policy in the United States emerged as a result of the activism of Dorathea Dix, in the mid-19th century. Her work was primarily concerned with the absence of any standard of care for impoverished and indigent people with mental health needs. The country soon entered an era of state-run institutions that provided shelter and treatment for such individuals. This policy of exceptionalism—the notion of creating special services and institutions for people with mental health needs—lasted roughly 100 years, until the emergence of a movement toward deinstitutionalizing and mainstreaming occurred in the middle of the 20th century. This mainstreaming era saw an emphasis not only on developing services in the community but also on serving more than just seriously mentally ill individuals, with an increased role of the federal government in shaping policy. The National Mental Health Act, signed in 1946, created a National Mental Health

Advisory Council and the National Institute of Mental Health (NIMH). The latter group focused on research and training that ultimately led to the development of community alternatives to hospitalization. The NIMH at that time sought to help individuals with mental health needs by developing resources directly in the community (Felix, 1949). Legislation followed in the late 1950s and early 1960s that promoted the development of Community Mental Health Centers, and debate grew regarding whether the evidence favored hospital-based or community-based treatment (e.g., NIMH, 1962).

The resulting 20 years of deinstitutionalization were characterized by controversy among policy makers and fragmentation of the service system. Many of the individuals for whom community centers had been created were not being served appropriately, while a newly identified population of individuals with less intensive mental health needs drew on those services. In 1977, President

Carter established the President's Commission on Mental Health, in the hopes of understanding and improving the existing mental health system. This Commission, however, was plagued by bureaucratic rivalries and ultimately did not produce the revolutionary and lasting change that was hoped for.

The next 10–15 years was characterized by numerous incremental gains in improving access to care, as well as system integration between hospitals and community services. During this time, funding for mental health services improved, largely through increased use of nonspecialty mental health sources, such as Medicaid. This shifted funding for mental health to agencies for which mental health was not the major concern. In 1992, there was a division within federal programs, with NIMH focusing primarily on research, and the Substance Abuse and Mental Health Services Administration being created for service development and policy functions. Around this time, federal focus increased on specific actions to create coordination and integration of care—including the now well-known demonstration project for children's mental health services in Ft. Bragg, North Carolina (e.g., Bickman et al., 1995).

A long-running theme over this nearly 150-year period of mental health policy involved a focus on equitable access to the best available services. Although debate often raged about the most appropriate methods, the primary focus of mental health policy in the United States has been to facilitate outcomes related primarily to community benefit and safety.

## The Influence of Psychology: Service Quality

The profession of psychology has played its own part in influencing mental health policy, emanating most recently from work in the early 1990s that was related to increasing pressure in the managed care environment to justify the costs of mental health services. In the midst of a long period of productivity on issues related to access to and coordination of mental health services, as well as parity to medical health, the 1990s saw an additional and initially somewhat independent focus on service quality and cost effectiveness. In the interest of establishing a working definition of service quality, in 1992, the American Psychological Association (APA) established the Task Force on Psychological Intervention Guidelines, chaired by David H. Barlow. This task force outlined a template for measuring the quality of psychosocial treatments, with the eventual goal of establishing guidelines for selecting the most appropriate mental health treatments. The task force outlined two dimensions—now widely known—along which treatments should be evaluated: (1) efficacy (i.e., how reliably a treatment is known to bring about change in a target disorder in clinical research), and (2) effectiveness (i.e., how well a treatment is expected to perform in a "real world" setting). These terms have been defined and discussed in detail elsewhere (e.g., Chambless & Hollon, 1998; Task Force on Psychological Intervention Guidelines, 1995).

As this APA task force concluded, Dr. Barlow requested that the Clinical Division of the APA build on this important foundation by establishing the Division 12 Task Force on Promotion and Dissemination of Psychological Procedures, chaired by Dianne Chambless. This Division 12 Task Force outlined a detailed definition of efficacy and developed an initial list of those psychosocial treatments with the best empirical support. The Division 12 Task Force published the first official list of empirically supported treatments in 1995 (Task Force on Promotion and Dissemination of Psychological Procedures, 1995), and has since published several updates (Chambless et al., 1996; Chambless et al., 1998). Eventually ushering in a national dialogue on *evidence-based practice* (EBP) in psychosocial treatment, these efforts within psychology have been profound and enduring in their influence on the nature of subsequent clinical training, research, and policy (Chambless & Hollon, 1998; Elliott, 1998; Glass & Arnkoff, 1996; Kazdin, 1996, 1998; Kendall, 1999; Kendall & Chambless, 1998; Nathan & Gorman, 1998; Nathan, Stuart, & Dolan, 2000; VandenBos, 1996; Weisz, Hawley, Pilkonis, Woody, & Follette, 2000).

Explicit in the early definition of EBP (initially described as "empirically validated treatments") were several important study features that afforded their treatments higher status: experimental control, replication, the use of treatment manuals, and clearly defined populations. Some of these features later came to embody significant controversy as the EBP paradigm began to shape practice policy, as will be reviewed later.

### *Benefits*

The benefits of this work by the APA and its Clinical Division have been substantial, laying the groundwork for policy and decision-making grounded in evidence and an increasing level of objectivity and accountability in a variety of domains. First and foremost are the implications for the diffusion of information about promising practices. The initial

list of treatments identified by the Division 12 Task Force has since spawned multiple successive movements and a diversity of evidence-based lists and registries (Chorpita et al., 2002; Lonigan, Elbert, & Bennet-Johnson, 1998; Silverman & Hinshaw, 2008; Substance Abuse and Mental Health Services Administration, 2008). Practitioners, researchers, and the public are now inundated with choices regarding how to select or identify an EBP, whether in books, chapters, state guidelines, federal guidelines, or online public and private registries and databases.

In terms of research, there is a new lexicon for establishing evidence of producing reliable outcomes—with most researchers now designing studies explicitly to meet the criteria for efficacy issued in 1995 (e.g., use of treatment manuals, randomized designs, independent replication). The result has been an improvement in many aspects of the quality of clinical research and research reporting over the past 15 years (see also Moher, Schultz, & Altman, 2001). Federal agencies are increasingly focused on research designs that build on this set of definitions and have, in many ways, sought to make EBPs a larger focus of the federal mental health agenda (e.g., U.S. Department of Health and Human Services, 1999; National Advisory Mental Health Council Workgroup on Services Research and Clinical Epidemiology, 2006; NIMH, 2008).

### Challenges

Although these developments with respect to service quality have been positive at the policy level, their practical implications have met with a host of challenges. For example, research has shown that treatment manuals—a core part of the definition of EBPs—have raised concerns on the part of many practitioners, who feel that manuals limit therapeutic rapport and the ability to flexibly tailor case conceptualization on an individual level (Addis & Krasnow, 2000). Interestingly, Nelson and Steele (2007) found that therapists' concerns with EBPs were not a function of negative attitudes toward research (viz. quality per se), but focused instead on reduced opportunity for clinical judgment and fears that research-based protocols do not fully address the complexity of real-world cases. Such findings suggest that practitioner objections are less a function of the direct emphasis on scientific support and more likely to be a side effect of the proposed definition of what constitutes a testable treatment (cf. Borntrager, Chorpita, Higa-McMillan, & Weisz, 2009).

Over time, a detailed array of arguments and concerns about EBPs and their policy implications developed into a significant antitheses, perhaps best summarized by Westen, Novotny, and Thompson-Brenner (2004). Longstanding concerns about the representativeness of clinical research and over-reliance on psychiatric diagnosis were combined with new concerns about the single-disorder architecture of most treatment manuals, inattention to comorbidity, inadequate control groups, and the perceived inflexibility of most evidence-based manuals (Norcross, Beutler, & Levant, 2006; Persons, 1991; Westen et al., 2004; Wolpe, 1989).

While the EBP movement and countermovement engaged in this healthy debate, national policy recommendations continued to emerge, whose integration with EBPs is often unclear. In 1999, the Office of the Surgeon General issued a report on mental health in the United States arguing, among other things, that promising treatments tested by science needed to be more available. At the same time, that report called for increased individualization of care and a need for services to be more consumer-driven, notions that could be considered difficult to integrate with manualized evidence-based treatments and sanctioned lists of scientifically approved interventions. Similar sets of recommendations followed in nearly every major national report or action agenda on mental health (and health more broadly) in the past 10 years (Hogan, 2003; Institute of Medicine, 2001; National Advisory Mental Health Council Workgroup on Child and Adolescent Mental Health Intervention Development and Deployment, 2001; National Advisory Mental Health Council Workgroup on Services Research and Clinical Epidemiology, 2006; Substance Abuse and Mental Health Services Administration, 2006).

Federal agencies are beginning to direct resources toward research on implementation and dissemination strategies (NIMH, 2008), in order to understand better what forces are involved with the successful impact of research-based treatments on communities. Similar to the dialectic regarding institutional and community-based care that characterized much of the policy discussions of the late 20th century, the current policy climate involves an interplay between two sets of ideals: (1) the objectivity, quality, and accountability associated with research-based protocols; and (2) the emphasis on consumer needs (e.g., occupational and social functioning), parity, access, and decision-making. Although both sets of ideals have the best interest of the public at heart, the pathway to their successful integration remains unclear, given the current structure of mental health delivery systems and laboratories that produce and

test interventions. In the remaining pages, we hope to outline what we see as two particularly compelling points of controversy, in the hopes of identifying strategies to address them, and we provide some example illustrations of possible ways forward.

## Problem 1: Organization and Emphasis of Research Findings

One fundamental goal of research is to serve public welfare in the long term by producing findings that are *cumulative*, such that one set of advances serves as a foundation for further work. To a significant degree, the history reviewed earlier demonstrates successful cumulative growth, and over a century-long span can be viewed as a gradual march toward equitable access to the best available services, adequately funded. Additionally, over the past 15 years, major advances have emanated from the efficacy criteria issued in 1995. The design standards enacted by these criteria make for enhanced comparability of results from diverse studies and prioritize independent replication, a necessarily cumulative endeavor. The resulting growth of the field has been powered in part by the decision of federal agencies to fund research designs that utilize these definitions.

However, to date, a major emphasis of the research community has also been on individual innovation. This emphasis is reflected in mental health by the proliferation of numerous successful treatment protocols (e.g., over 200 in children's mental health; Chorpita & Daleiden, 2009). The result is a fragmentation of innovation that stems from the complexity of using the evidence base as a guide to selecting a quality treatment protocol for the purpose of training staff or treating an average client. Hundreds of randomized clinical trials exist to inform such decisions; however, these trials have produced a comparably large number of successful protocols that are unique in the strict sense of scientific replication (see Chorpita, Daleiden, & Weisz, 2005a). These various protocols each have evidence of efficacy only with certain populations. Selecting a protocol with the goal of maximizing the fit of the intervention with the problem and context of an individual client or the client population typically served by an agency thus involves making difficult decisions. Given the large number of similar but unique protocols, interpretation of the evidence base depends on discerning which approaches are sufficiently similar such that their findings can be aggregated. To illustrate with an example, one might ask whether findings in a trial of a leading youth anxiety protocol, the Coping Cat (Kendall, Kane,

Howard, & Siqueland, 1990), can be aggregated with those of an adapted Australian version, the Coping Koala (Barrett, Dadds, & Rapee, 1991), or whether those findings can also be aggregated with those of other studies testing youth anxiety protocols based upon similar cognitive behavioral principals and strategies (e.g., Barrington, Prior, Richardson, & Allen, 2005; Masia-Warner et al., 2005). There is, at present, no policy regarding a uniform standard for aggregating scientific information to inform mental health practice, and this affects not only the ability to leverage existing federally funded research, but also the quality of ongoing and future research reporting.

A major question to be addressed is, thus, whether the current emphasis on individual innovation in the treatment development area continues to serve the long-term goal of serving public welfare via cumulative growth of the field. First, it is important to recognize that the current incentive structures reward researchers and developers for specialization, and that many of these contingencies are influenced, directly or indirectly, by federal research policy. For example, tenure, promotion, and grant resources are attained through voluminous research output and demonstration of expertise, both of which are most readily achieved via specialization: the crafting of a niche area of endeavor, and replication of success within that area. In mental health treatment research, this often involves the design of a new treatment, incorporating many elements of existing treatments, but adding new elements as well, and packaging them into a unique whole. Incentive structures implicitly encourage this creation of new treatments even when a large number of effective protocols already exist in a particular area. Studies replicating the success of an existing treatment created by another researcher afford relatively less reward or opportunity; whereas the creation of a new treatment that proves successful in a clinical trial may offer the opportunity for further study by its designer, as well as additional opportunities if the treatment is eventually adopted by others. Mental health treatment researchers are thus generally rewarded for creating a new treatment, studying that treatment, and promoting it as distinct and superior to other existing treatments.

This individual-specialization model has been useful to the field, in that it has produced a large number of efficacious and sophisticated treatment technologies. However, a problem with the emphasis on individual innovation is that it tends to create relatively isolated "silos" of research, and ultimately silos of treatment technology available for consumers.

Certainly, investigators do incorporate aspects of others' advances into their own work. However, the incentive structures described here encourage researchers to emphasize the differences between their own and others' work, without a balanced emphasis on the commonalities and compatibilities. Additionally, career success may be maximized by protecting one's own research product, replicating success only in safe environments, producing further investigation within a controlled, restricted realm, or looking mainly at measures most sensitive to change (i.e., symptoms) regardless of their importance to consumers. Efforts to protect such work may also expand to preventing it from being adapted into the work of others or tested in ways that expose weaknesses. The cost to the field here is the relative isolation and even irrelevance of the resulting lines of research. Towering advances exist, but they stand as silos, separated from other areas of research that will ultimately be essential to advancing real-world applications for the public benefit.

To be clear, the isolation of treatment research from dissemination and implementation know-how is not specific to any protocol but rather endemic throughout the field, affected in part by a federal research policy that has not fully anticipated the changing landscape of accumulating treatment research. At the very least, it is a lack of a policy addressing the consequences of specialization that has played a role. This potential for inefficiency is especially salient in the context of a field that generally sees a 15 to 20-year gap between research innovations and changes in practice (Institute of Medicine, 2001).

### Potential Solutions: Emphasis on Collaboration, Compatibility, and Common Architecture

An alternative to the emphasis on individual innovation, design, and replication is a new, more rigorous emphasis on cooperation and compatibility. One method of combating fragmentation is via research *networks*, in which researchers collaboratively design programs of broader scope and greater scale than can be achieved by any individual laboratory alone. Although informal collaboration among small groups of researchers is common throughout the field, the majority of treatments available did not emanate from formal collaborative networks. Exceptions do exist. In the private sector, the Resource for Advancing Children's Health Institute's (REACH) is a nonprofit organization with a focus on treatment dissemination in children's mental health. Its members participate in the associated Integrated Psychotherapy Consortium

(IPC), a collaboration of many leading treatment developers and researchers. Additionally, the MacArthur Foundation, one of the nation's largest private granting agencies, has sponsored a number of research networks in mental health areas, including Youth Mental Health, Mental Health Policy Research, Mind–Body Interactions, and Psychopathology and Development. An example of a federally organized collaboration is the National Child Traumatic Stress Network, which combines academic and community-based service centers with the mission of raising the standard of care and improving access to services for traumatized children via training, direct provision of clinical services, and collaboration with established systems of care.

The most significant obstacles to the success of these types of networks relate to the issues of incentive structures mentioned earlier. A natural difficulty concerns compromises about the research designs, as well as significant increases in time and complexity associated with collaborative networks. Planning and coordinating a large integrated operation, often across long distances, entails ongoing, complex communication, much beyond that associated with research in an individual laboratory. However, little direct reward comes from excellence in these areas per se; indeed, effective communication may easily be neglected amid efforts to satisfy more immediate demands of developing and testing mental health treatments. As explored further later, for research networks to be more a widespread and common part of the landscape, incentive structures have to change on a broad scale.

A second way in which cumulative research progress can be achieved through an emphasis on cooperation is through the use of common standards or common architecture. The principle here is that consumers tend to benefit when developers can agree on a design standard. Common standards can be either proprietary or open, and examples are quite common in areas outside of mental health treatment. An example of a proprietary standard is the Blu-ray digital disc format. Recent de facto agreement on Blu-ray as the next-generation disc format has allowed producers of discs and disc players to commit to the format, producing a wider array of compatible products at a substantially lower cost than was previously possible, thus creating benefit for consumers. Other examples of proprietary standards and architectures include proprietary computer operating systems, radiological image storage and viewing systems, and selected digital media file formats, as well as a plethora of more mundane

products ranging from vacuum cleaner filters to razor blades to printer ink cartridges.

Examples of open standards are those published by the World Wide Web Consortium (W3C), an international group that develops standards and guidelines with the mission of preventing fragmentation of the Web by promoting interoperability (World Wide Web Consortium, 2008). The W3C is organized as a consortium, with paying member organizations obtaining a seat on an advisory committee and participating in other capacities of standards development. Standards published by the W3C include HyperText Markup Language (HTML), the predominant means of structuring text and forms on Web pages, as well as a large number of compatible and widely used open technologies such as media formats and standards for Web applications and security. The existence of these standards has been instrumental to the rapid growth of the Internet (Branscomb & Kahin, 1995). Other examples of open standards and architectures include the Unix (and Unix-like) computer operating systems, voltage and socket standards for U.S. appliances, and television and radio broadcast standards. Notably, the use of open standards does not indicate that a market is noncommercial. Rather, as with the proliferation of commerce on the Web, businesses may thrive by selling unique products that function via compatibility with an open architecture.

Applying common standards or common architecture to the design of mental health treatments may also hold potential for major benefits to consumers. A common standard or common architecture for treatment protocols could take a variety of forms. One model is provided by the integrated approach to manual design of the REACH Institute, mentioned earlier. REACH offers manuals for each of four common youth disorder areas (e.g., Integrated Psychotherapy Consortium, 2005). These manuals feature an integrated design with standardization of session organization, terms, and techniques across manuals. Additionally, each manual includes a small list of additional sessions from the other problem areas that may be utilized as needed to supplement treatment (e.g., a session titled "Changing Negative Thoughts" from the depression protocol may be used to supplement the anxiety protocol). The manuals can thus be used in combination to address comorbidities with greater ease than is possible with stand-alone single-disorder manuals.

REACH's integrated approach offers potentially significant advantages in terms of compatibility and transferability of competencies. These advantages could be multiplied were the architecture to become a widely adopted standard. Wide adoption by other treatment designers could mean compatibility across a greater number of problem areas and multiple compatible manual options within single problem areas, allowing providers to choose preferred manuals without sacrificing compatibility. However, despite these potential advantages, some of the drawbacks associated with traditional standalone manuals remain. Notably, the REACH manuals are subject to the common problem of updating material: changing its content requires creating a new version of an entire manual (or perhaps of multiple compatible manuals) and thus can be undertaken only rarely.

We have argued elsewhere that greater steps toward achieving common architecture can be taken through the use of a modular approach to treatment design, as opposed to the conventional, or integral, approach represented by most manuals today (Chorpita, Daleiden, & Weisz, 2005b). In modular treatment design, a complex treatment is organized into smaller subcomponents, referred to as *modules*. Key features of a modular design include the fact that each module has a specific function (e.g., a relaxation module aims to reduce autonomic arousal), and each module implements a standardized interface to allow smooth connection with other modules (e.g., communicating information required for reviewing assigned homework in the following session). Additionally, modules can be of two types: (1) content modules, that represent the building blocks of the intervention, describing the therapeutic activities to be performed (e.g., teaching relaxation) and are similar to procedural descriptions in typical therapy manuals, and (2) coordination modules, that outline the decision-making algorithms regarding whether and when to apply the various content modules. Although modular design has a wide array of potential advantages, as well as disadvantages, in comparison to integral design (Chorpita et al., 2005b), most relevant here is the ease of incremental improvement. Whereas changing an integral design requires examining a treatment procedure from beginning to end, a modular design allows updating of a single piece. Thus, a researcher could contribute a module representing a particular innovation—say a new relaxation technique—with minimal design overhead. This potential advantage makes modular frameworks strong candidates for a common architecture, and potentially organizes innovation in such a way as to impact consumers more quickly and effectively.

A common architecture could be achieved in a modular framework via specification of an interface

for all intervention components (content and coordination modules) to implement. For content modules, the interface would indicate the types of information the modules must be capable of communicating (e.g., the type of homework assigned, if any, and how it is to be reviewed), as well as the structure of the therapeutic activities to be performed (e.g., each step listed with a title, a brief summary, and detailed description if appropriate). The interface may also specify certain required components that the content module must implement (e.g., when appropriate, bridge from previous session and review homework). Additionally, the interface may provide a format for types of "meta-data," (ADL, 2003) or information about the module itself, to be included. Examples of meta-data are description of a module's purpose, the age or cultural limitations of its application, constraints regarding its sequencing within a protocol, references, and information regarding ownership/authorship (Chorpita Daleiden, & Weisz, 2005b). For coordination modules, in addition to structuring meta-data similar to that of the content modules, the interface may define the manner for representing information, such as the sequencing of content modules, the decision points in sequencing, and the information sources used to guide decisions.

Returning to a broader level of discussion, it is important to emphasize that the goal of a common architecture is to encourage more cumulative growth of mental health treatment knowledge by allowing contributions from different designers to be combined in meaningful and effective ways and by providing a framework for collaboration and shared incentives for treatment developers. The potential advantages that modular treatment design frameworks offer in comparison to integral frameworks, particularly the efficiency-related advantages of reusability and ease of updating, reorganizing, and combining modules, seem to make modular frameworks well suited for this goal.

However, even with a modular framework, significant challenges would have to be overcome to create and maintain an open architecture that serves this goal. For example, the most common method of disseminating mental health treatment procedures to practitioners remains published books and manuals (unfortunately, a major incentive for treatment developers). These are by nature more challenging to update and/or aggregate. At present, no clear standard exists for how to codify treatment procedures efficiently that allows for incremental updates as well as multiauthor collaboration.

As noted earlier, shifting the field's research emphasis from individual innovation to cooperation and collaboration will require significant change to incentive structures. Within academic research institutions, increasing recognition would need to be given for collaboration and work supporting cumulative growth. Encouragement of collaboration through research networks would require some shift in funding priorities from government agencies and private foundations. Similarly, for common architectures to flourish, grant-funding priorities would need to emphasize projects that are compatible with a consensually defined common set of standards. Achieving consensus on such a standard would be a great challenge. A standard could be imposed in a "top-down" manner via government intervention or via the recommendation of a consortium of relevant stakeholders (similar to the W3C described earlier). Alternately, a standard could evolve in a "bottom-up" manner via demand from mental health provider organizations for treatments compatible with their existing investments in staff training, instrumentation, and technology.

## Problem 2: Scaling for Implementation

Aside from problems that stem from research principles and policies that continue to privilege specialization and individualism over coordinated standards, an entirely separate problem remains regarding the lack of a dedicated product dissemination network in mental health.

As discussed in the introduction, nearly every major national report or action agenda on mental health in the past 10 years has emphasized that promising treatments tested by science need to be made more available. Although federal agencies are now beginning to direct resources toward research on implementation and dissemination strategies (NIMH, 2008), the field is still in the early stages of gathering knowledge regarding the challenges involved in bringing research-based treatments to communities. A major open question, then, is how to scale practices effectively from the research level to the national level (see Fixsen, Naoom, Blase, Friedman, & Wallace, 2005).

Before considering how to guide policy to encourage scaling practices for implementation, it is valuable to consider the ways in which practices are scaled in the current mental health landscape. The most common paradigm for treatment production and scaling in recent years centers around manual publication. The routine chain of steps and corresponding incentives involved in dissemination involve the development and testing of a treatment in an academic research laboratory, often utilizing

public funding via granting agencies. Incentives for this work exist for the academic investigator who develops the treatment and conducts the research. A second step is for the successfully tested treatment to be published as a manual, then distributed and promoted via existing channels (e.g., stocking on bookstore shelves and promotion at research conferences and via mailings). The incentive for this step is profit from sales for both the publishing house and the treatment manual's author(s).

In many cases, the current chain breaks down at this second step. To begin with, provider concerns about treatment manuals (e.g., Addis, Wade, & Hatgis, 1999) may be a disincentive to learning new treatments through this medium. Further, most treatment developers acknowledge that the purchase and application of a treatment manual is insufficient for one to learn a new practice (e.g., Henggeler & Schoenwald, 2002), and most research on adult learning demonstrates the importance of coaching and supervision/feedback for new practices to take hold. Thus, the end-product of much federally sponsored research designed to improve the quality of mental health services ends up on clinicians' bookshelves (or worse, unsold in bookstores), and rarely makes its way to affecting the lives of mental health consumers.

In places where exceptions exist, it is often through highly entrepreneurial and ambitious efforts on the part of developers who have successfully commercialized their approaches, despite a lack of policy-based incentives for doing so. Multisystemic therapy (MST; Henggeler, Schoenwald, Borduin, Rowland, & Cunningham, 1998) is perhaps the strongest example of successful diffusion for an evidence-based treatment (Drake, Skinner, & Goldman, 2008). Multisystemic therapy is a family-based treatment for youths with severe antisocial and other clinical problems, delivered in the home and community. First developed and evaluated around 1990, MST has spread to currently serve 16,000 families a year in 32 states and 10 countries (Drake, et al., 2008). This scaling success has been achieved in part via the creation of a technology transfer organization, MST Services, Inc., which is affiliated with the treatment's university research center of origin. MST Services, Inc. has established many high-fidelity implementation sites by engaging in a long list of implementation activities, including site assessment, orientation training at a central location, weekly telephone consultation and quarterly booster trainings, evaluation of monthly adherence data, and support with both administrative and larger system issues, such as interagency collaboration (Schoenwald, Brown, & Henggeler, 2000).

This success in producing numerous high-fidelity implementation sites provides a valuable example. However, it is important also to note that, despite this success, after nearly two decades, MST adoption remains small in relation to need. Drake and colleagues (Drake et al., 2008) identify both financial and system compatibility barriers to MST's greater diffusion. Regarding financial barriers, the cost of training and financing the intervention are formidable. Although MST has been associated with overall cost savings, incentives may encourage agencies to shift relevant youth to others' budgets rather than serving as an authority for these difficult cases.

Regarding system compatibility barriers, Drake and colleagues note that MST imposes strong requirements for new skills and business practices, and may present a real threat to existing programs and systems of care. Additionally, as Henggeler and Schoenwald (2002) indicate, a large set of problematic contingencies act on providers of care at the practitioner, organizational, and community levels. Examples include productivity measures based primarily upon hours of face-to-face therapist–client contact, and reimbursement mechanisms favoring group and facility-based treatment over individualized evidence-based and intensive community-based treatments. These forces limit the range of sites that can be considered for MST implementation without major structural changes.

A critical aspect to highlight from the example of MST is that a great deal of effort, resourcefulness, and ingenuity was required to conceive of and build its complex implementation organization. MST Services, Inc. states that this effort was undertaken when "the burden of disseminating the MST model to interested communities began to have a detrimental impact on the research productivity" (MST Services Inc., 2008). The MST research team engineered a way to transform this burden into a successful implementation arm dedicated to the intricacies of the technology transfer process. However, in the face of similarly burdensome obstacles to dissemination and implementation, many treatment research teams have instead fallen back on academic travel-and-train approaches, with insufficient time and personnel resources to have a truly large or lasting impact—even with treatments that are quite promising and likely to serve the mission of increased service reliability. There are many understandable reasons for such a choice. Indeed, the incentive structures discussed earlier pressure researchers to

pursue specialization, and efforts directed at implementation are outside most treatment researcher's area of expertise. However, the need for the invention of MST's implementation arm should also draw attention to the absence of an existing structure for scaling many effective treatments for other populations.

Although both state and federal infrastructure exists to support treatment developers in dissemination and implementation (e.g., Substance Abuse and Mental Health Services Administration and the California Institute for Mental Health), such mechanisms have not entirely addressed the training workforce problems, instead choosing to promote and support those approaches that have independently developed training divisions. These groups must "reinvent the wheel" to build a dissemination solution. The absence of a dedicated workforce for dissemination is exemplified by EBP's most widely researched treatment modality, cognitive behavioral therapy (CBT). No authoritative large-scale resource exists to service institutions that want to train their staff to provide adult CBT. One notable resource, the Beck Institute, provides workshops and year-long programs for therapists and supervisors, and features training from one of CBT's founding figures, Aaron T. Beck. However, like other existing training programs, the Beck Institute can serve only a small population.

For evidence-based treatments to become widely available, the task of dissemination and implementation will have to be transformed from a treatment-developer's burden to a sophisticated enterprise, leveraging broad networks of knowledge and support. Ways to approach this goal are explored below.

### Potential Solutions: Dialogue on a "Practice-Centered" Approach, Implementation Workforce, and Economic Incentives

Summarizing the problem just described, the current paradigm for dissemination of high-quality treatments represents a broken chain, terminating at the link of manual publication. Few structures or support systems exist to provide scaffolding for dissemination and implementation efforts. Instead, treatment producers seeking to reach communities must reinvent the wheel, undertaking major efforts outside their areas of expertise. Few have succeeded in this difficult task.

Solutions to such problems require a shift in policy, from emphasizing development of quality treatments,

as noted earlier, to installing and implementing them in a sustainable manner. Such a shift has significant implications for the culture of training and service delivery. For example, Fixsen et al. (2005) characterize the status quo in mental health as being "practitioner-centered" as opposed to "practice-centered." By that, they mean that the services available to consumers are largely a function of each individual provider's unique training history and experiences. By contrast, Fixsen et al. describe a "program-centered" or "practice-centered" approach as one that involves systems characterized by well-defined practices, theory, and values, in which practitioners are participants. In the practice-centered approach, it is the agencies and systems that define and sustain what services are delivered, rather than the sum of individual practitioners. Thus, the system defines the standard of care, and the practitioner is hired to participate as an agent in the delivery of that care.

Within psychology, this is a radical shift in philosophy within graduate training and continuing education programs, which implicitly position practitioners to be individualist-experts rather than agents of a larger professional system. Although the Individual-Expert Model has served the field and the public well for the past 50 years, the field has changed in terms of the availability of mature, integrated evidence-based service programs. In light of these new developments, the models that characterize many of the field's best training programs now may overemphasize the role of clinician as developer and tester (e.g., the Scientist-Practitioner Model). Given the developing stock of robust, high-quality treatments, at least an equal emphasis may be needed to prepare psychologists to understand better the implementation processes and clinical management structures of common EBPs. The workforce demands of the future are more likely to require individuals who can participate in delivering, training, evaluating, and sustaining practice models that are already highly developed. Given how the field has evolved, federally sponsored agendas should be developed to explore and define training models that are more conducive to the changing ecology of mental health service delivery, much in the way the Scientist-Practitioner Model was established and then promoted in the mid 20th century.

Aside from the need to address problems with an increasingly outmoded culture of professional training, there is an even greater need to develop an implementation industry in its own right. Making high-quality, evidence-based treatments widely

available will require the creation of a support system. Addressing this very topic, Fixsen et al. (2005) drew a striking analogy in the area of computer science. As hardware and software continued to develop and improve in the computer industry, government and businesses began to adopt particular platforms, invest in refinements and improvements, and staff a workforce for maintaining and sustaining such platforms. It is now standard practice for government agencies and all but the smallest businesses to have information technology (IT) departments or divisions, which are dedicated to the continual upgrading, refinement, and problem-free operation of the latest technologies. This professional architecture is largely absent from mental health services, with the majority of innovation occurring de facto due to the often incidental hiring of new staff into leadership or supervisor/trainer roles. Simply put, there needs to be a dedicated arm of the workforce—whether seated in government, third-party payers, or service agencies—that plays the innovation and sustainability function analogous to IT departments in most industries. The "software" of mental health services, its evidence-based practices and programs, has matured to a point similar to where operating systems, word processing, and statistical spreadsheet software were in the late 1980s.

This raises the question of where an implementation and maintenance workforce will come from, and what precise form it will take. Indeed, in much the same way that the IT support industry has developed a diversified and robust career trajectory for computer science majors, such a pathway will need to come into better focus in mental health. The current state of affairs is that such responsibilities for implementation and maintenance continue to fall to the treatment developer. That is, the largest and most successful evidence-based programs have developed implementation arms to their research and development programs. Such a strategy may ultimately run up against issues of scale, and is analogous to having a software developer such as Microsoft handling the installation of its own software and the management of local technical support. In the ideal world, the highest-quality practices would be available on a scale far too great for developers to play a significant role. It is plausible that no treatment developer currently has the capacity to initiate and staff a national implementation agenda for its programs, let alone to make sense of how those programs will mesh with other programs being adopted (as reviewed earlier). A whole new industry is needed to implement and coordinate the massive-scale implementation efforts needed to close the gap between science and practice.

Some early indications of such independent implementation structures have emerged, although it remains to be seen what will define an industry standard. For example, California has had a government-sponsored structure in place for 16 years—the California Institute of Mental Health (CIMH)—dedicated to promoting excellence and innovation in the state's mental health services. In 2001, the CIMH began efforts to introduce EBPs into the state system. The Institute has recently established a development model, the Community Development Team Model (Sosna & Marsenich, 2006), that established a statewide structure with the aims of providing information on EBPs, providing technical assistance to agencies implementing those practices, consulting directly with developers on best strategies for dissemination and innovation efforts, supporting social networks for continued communication about practices, and creating mechanisms for sustainability of adopted practices. A major benefit of this approach is that it houses much of the responsibility for implementation within a single organization, rather than with developers whose focus may be on treatment innovation, research, and evaluation, or with providers whose focus is first and foremost on service delivery. Many other initiatives exist across the nation, with each taking a somewhat different shape. For example, Ohio has established a Center for Evidence Based Practices within Case Western Reserve University, charged with fostering implementation of evidence-based approaches, whereas New York's Office of Mental Health and Hawaii's Department of Health, for example, have government-driven initiatives that leverage local university partnerships. Other models continue to emerge, but the larger message with respect to policy is that a national dialogue has come due on which of these structures are proving to be most useful, a dialogue that should include input from researchers and experts in system change and organizational innovation, both in mental health and in other fields.

Finally, there is the issue of incentives. Profitability is thus often an engine for overcoming informational barriers through advertisements and other promotional activities. Drake and colleagues (2008) cite the example of naltrexone, a drug used in the treatment of alcoholism, whose story demonstrates a failure of diffusion in the absence of profitability. This drug is available in generic preparations and thus incentives for marketing are absent. Despite efficacy

having been demonstrated in 29 placebo-control trials (Pettinati et al., 2006), and over a million Americans receiving treatment for alcoholism in medical care settings, the average number of naltrexone prescriptions per month was 14,000. Drake and colleagues (2008) point out that the lure of profitability can also lead to problematic wide adoption in the absence of good evidence, as in the case of second-generation antipsychotic medications for schizophrenia. Prior to the availability of well-designed trials to compare the second-generation antipsychotics to the first-generation medications, the pharmaceutical industry convinced government agencies to pay for these drugs at the expense of diminished funding for evidenced-based services such as housing programs. When evidence matured, the new second-generations medications were found to be no more effective than the older antipsychotics (Lieberman et al., 2006). Thus, incentives play an important role in determining what services reach the consumer. An open dialogue regarding these issues is difficult, given that profitability and economic incentives are somewhat taboo topics within academic mental health, and yet a new paradigm needs to emerge that supplants or extends the current approaches of (a) publication of book-length treatment manuals in exchange for royalties, (b) time-limited government sponsorship of isolated dissemination efforts, or (c) university clinical laboratories acting as dissemination agents. Again, it is not clear what shape that new paradigm will take, but it is clear that a nationally sponsored dialogue on the issue is overdue.

## Conclusion

The long history of mental health policy in the United States has principally served the issues of availability, access, and parity of mental health services, with an increasing focus on the real-life outcomes that matter to consumers and structures of delivery that reflect the values of community- and family-centered approaches. While dealing with the questions of where, to whom, and how much, mental health policy has yet to play the same significant role with respect to the question "of what quality?" This relative neglect is an understandable consequence of the still very recent EBP revolution and its implication for service quality. This revolution is our generation's policy battle, just as the creation of asylums for the indigent and mentally ill was in the late 1800s and just as deinstitutionalization was in the mid-1900s. The complexity of leveraging science to optimizing or even just improve service has proven to be substantial,

and we inherit training, service delivery, insurance, and government structures that were not originally developed with these new aims in mind. We are fortunate that such a problem confronts the field— there are now more high-quality, evidence-based practices and programs than can be successfully integrated and for which there is a workforce to implement. The pace of progress in treatment development and refinement is likely only to increase, so it is time to turn our attention nationally to how best to take advantage of such bounty, especially now when most of those quality programs and practices still never make it to the consumer.

# Unified and Transdiagnostic Conceptions and Treatments for Psychopathology and Pathophysiology

# Interviewing and Case Formulation

Naomi Koerner, Heather K. Hood, *and* Martin M. Antony

**Abstract**

The main objective of this chapter is to provide an overview of clinical interviewing. Although clinical interviewing is often referred to as an art (Shea, 2007), the information in this chapter highlights the science of clinical interviewing as well. The chapter opens with a discussion of the general structure and content of clinical interviews that are typically conducted in mental health contexts. The reader is introduced to a variety of interviews that are used in the assessment of Axis I and Axis II conditions, including their psychometric properties; guidelines for the assessment of suicidality are also presented. This is followed by an overview of interviewing skills. Specifically discussed are ways in which information processing limitations, verbal and nonverbal cues, and style of questions can influence the clinical interview. We then turn to a discussion of case formulation, a core component of the clinical interview. Empirical research on the impact of training on quality of case conceptualization and on the association between case formulation and treatment outcome is summarized. The chapter closes with a brief overview of issues that may arise when interviewing certain populations, in particular, couples, individuals from diverse populations, and young individuals.

**Key Words:** Case formulation, clinical interviewing, couples, diagnostic interviews, diverse populations, interviewing skills, suicide risk assessment, young clients

## The Clinical Interview: An Introduction

The clinical interview is one of the most essential elements of psychological care. Although it is just one component of a comprehensive assessment, it is often the first opportunity for client contact and is the foundation for subsequent treatment. Unlike many other assessment tools, the interview allows the clinician to explore the idiographic or unique nature of an individual's experience, including any or all of the following: symptoms; observable behavioral features; degree of distress and functional impairment; development and course of the problem; relevant personal and family history; and goals for treatment. The richness of data collected may aid in matching the client to treatment, increasing the likelihood that the client will receive the most effective intervention (Yates & Taub, 2003). Sommers-Flanagan and Sommers-Flanagan

(2009) suggest that it is "ill-advised, unprofessional, and potentially dangerous" (p. 7) to initiate treatment without first conducting a suitable assessment. In fact, research suggests that the clinical interview itself may confer some psychological benefits to the client (Finn & Tonsager, 1997).

The prominent role of clinical interviewing in the management of psychological distress highlights the need for an understanding of the nature of the clinical interview. The interview is multidimensional in nature, integrating intrapersonal, interpersonal, and theoretical factors. One's clinical judgment and, therefore, the validity of the clinical interview can be enhanced by an awareness of intrapersonal factors including, but not limited to, personal biases, overconfidence in one's diagnosis, and tendency to search for information that confirms this diagnosis

(Arkes, 1981). Concurrently, the clinician must be mindful of the interpersonal dynamic with the client. Establishing good rapport and obtaining accurate information in part depends on the client's feeling that the information conveyed is done so in an atmosphere of confidentiality, understanding, and respect (Kremer & Gesten, 1998; Turner, Hersen, & Heiser, 2003). Finally, an accurate assessment requires the clinician to be knowledgeable about psychopathology and the psychological conditions being assessed. Balancing these factors, while remaining aware of the purpose of the interview, requires a high degree of skill, knowledge, and training on the part of the clinician.

The clinical interview may be a diagnostic, risk-management, treatment, or research tool, or any combination thereof. Thus, the purpose of the interview is highly dependent on the setting in which it occurs. The clinical interview in a hospital emergency room or crisis center will look much different than one conducted in an outpatient clinic or private practice. In emergency situations, the priority is often to quickly assess the risk of violence or suicide, perhaps with the goal of making a determination about the need for hospitalization or immediate medical intervention, rather than a precise diagnosis. Conversely, clients presenting to an outpatient treatment and research clinic often receive a comprehensive assessment, in which the clinical interview may be accompanied by self-report questionnaires, monitoring diaries, behavioral assessments, and physiological measures (Antony & Rowa, 2005). Interviews for the purposes of long-term therapy planning may span several sessions aimed at developing the therapeutic relationship and obtaining a detailed personal history and thorough understanding of the client's presenting problems. Although the precise purpose of the clinical interview will depend on the setting in which it is conducted, the goal is always to develop a greater understanding of the client's experience and level of psychological functioning.

The purpose of the interview and the setting in which it is conducted largely determine the type of interview to be used. Unstructured interviews, also referred to as traditional interviews, engage clients in a flexible manner. The course of the interview is variable; the questions are selected entirely at the discretion of the clinician, who is guided by the responses of the client to explore areas of interest and determine a diagnosis (Summerfeldt & Antony, 2002). This approach has been credited with increasing rapport with the client, enabling quick decision-making in crisis situations, and validating the client's

experience (Groth-Marnat, 2003). However, the lack of standardization has been criticized for compromising reliability and validity. Research has shown that inter-rater reliability is low with unstructured interviews; that is, two clinicians with similar training often assign different diagnoses (Ward, Beck, Mendelson, Mock, & Erbaugh, 1962). The phrasing, focus, and sequencing of questions affect a client's interpretation and response, introducing a considerable amount of variance into the process (Rogers, 2001; Ward et al., 1962). Further, although the unstructured interview explores some symptoms in depth, it often lacks breadth of questioning, resulting in an increased risk of missed diagnoses (Rogers, 2001; Zimmerman & Mattia, 1999a).

The structured interview, on the other hand, is a systematic approach to interviewing that uses standardized questions and responses options. This format resolves many of the psychometric limitations of unstructured interviews, and it has been argued that it improves the diagnostic utility of the clinical interview (Rogers, 2001). For example, Ruegg, Ekstrom, Evans, and Golden (1990) found that the use of structured mental status exams resulted in higher-quality and more comprehensive assessments compared to the unstructured format.

Structured clinical interviews are often organized according to symptom clusters, allowing the clinician to quickly screen for the presence or absence of symptoms or disorders, and to focus the interview on specific areas of interest (Summerfeldt & Antony, 2002). The efficiency of this method increases the breadth of the assessment, obtaining the most relevant information needed to make an accurate diagnosis in the least amount of time. Structured interviews also vary greatly in their degree of structure. In highly structured interviews, such as the *Diagnostic Interview Schedule* (DIS-IV; Robins, Cottler, Bucholz, & Compton, 1995), questions are read verbatim from the manual and responses are coded according to the available response options. The interviewer is not permitted to include follow-up questions, aside from those provided in the administration manual. Critics of structured interviews suggest that such a format may overlook the "idiosyncrasies and richness of the person" (Groth-Marnat, 2003, p. 77) and interfere with rapport; however, others argue that this may only be the case if the interviewer is unskilled in the administration of the test (Rogers, 2001).

As the name implies, semi-structured interviews are an amalgamation of traditional and structured interviews, capitalizing on the psychometric strengths

of the structured format while maintaining the flexibility to include additional probes as necessary. Such interviews are common in research settings, and are becoming more common in clinical settings because of the quality of the information obtained (Summerfeldt & Antony, 2002). All means of interviewing have assets and limitations, and it is therefore unwise to dismiss out of hand any one format. The perception that one must choose between structured and unstructured formats represents a false dichotomy, or what Rogers (2001) refers to as the "either/or" fallacy. Structured and unstructured interviews provide useful information for an accurate assessment of the individual.

The clinical interview is critical to the mental health care process. It is multidimensional in nature and thus requires a high degree of skill and knowledge on the part of the clinician. The information provided in this chapter will aid clinicians in selecting the appropriate type of interview to meet their needs, using interview data for case formulation, exploring strategies and skills to enhance the clinical interview, and in discussing ethical and professional issues relevant to the interviewing process.

## Overview of the Interview Structure

Although the format, content, and flow of the interview are determined by the type of interview, all clinical interviews share common elements. Variations in the structure of interviews have been proposed (e.g., Foley & Sharf, 1981; Shea, 1998), but there is general agreement that assessment sessions consist of an *opening*, *body*, and *closing*. Prior to the session, several preliminary steps set the stage for a successful interview.

### Initial Steps

The assessment process begins at the moment of first contact with the client, often at the time of scheduling the appointment. Whether conducted by administrative personnel or by the individual carrying out the interview, this is the first step in developing rapport; therefore, it should be done in a professional and collaborative manner. Managing first impressions is critical at the beginning of the interview. As the clinician presents his or her credentials, it is an opportunity to establish authority, instill confidence, and set boundaries for the remainder of the session. This can be particularly challenging for clinicians-in-training. Generally, clinicians are advised to use their first and last name when introducing themselves and to follow this with a brief description of their credentials (e.g., "Hello, my name is Pat Smith; I am a psychology intern here at Clinic X, and my supervisor is Dr. Brown, a licensed clinical psychologist"). Students are encouraged to present their credentials in a confident and straightforward manner; however, they should be careful not to overstate or misrepresent their qualifications, as this constitutes an ethical violation (Sommers-Flanagan & Sommers-Flanagan, 2009). Students should be direct and honest in their presentation of their experience and current status (e.g., "I am in my second year of a master's degree in clinical psychology and this is my second psychology placement"; "I am in the third year of a doctoral program in clinical psychology, and I am working here at Clinic X as part of my training").

Many clinicians in the early stages of their training may not be sure how to address their client. The most prudent approach is to address clients by their title and last name (as in, "Mr. Jones" or "Ms. Lee"), rather than addressing them immediately by their first name. Some clients may readily indicate that they would prefer to be called by their first name, while others may not. Clinicians can ask clients about their preferences if they are uncertain (e.g., "Would you prefer that I address you as Ms. Lee, or Sam?").

The physical space also contributes to a client's first impression of the upcoming session. Although the physical space will be determined in large part by the clinical setting, some features of the room may facilitate the interview process. At the very least, privacy is crucial, and interruptions should be avoided. This reaffirms the confidentiality of the procedure and increases client self-disclosure (Sommers-Flanagan & Sommers-Flanagan, 2009). In addition, the interviewer should have control of the environment, in order to establish professional boundaries, although the client should have minor choices such as seating arrangements (Sommers-Flanagan & Sommers-Flanagan, 2009). Some recommend a 90-to-120-degree angle seating arrangement (Sommers-Flanagan & Sommers-Flanagan, 2009), which allows for flexible eye contact for both parties. Others prefer a face-to-face arrangement for the intake interview, with a desk between the interviewer and client, thus differentiating an assessment from a therapy session.

### Opening

The goals of the opening phase of the interview are to convey essential information (such as confidentiality), to obtain informed consent, to alleviate anxiety, to develop rapport, and to set the tone of

the interview. Confidentiality is a right afforded to all clients as mandated by law, and clinicians are not permitted to disclose information obtained during the assessment without the client's consent. However, there are conditions under which the clinician is ethically and legally obligated to break confidentiality. The specific conditions are established by one's professional governing body (e.g., American Psychological Association [APA], 2002) and legislative guidelines. It is the responsibility of the interviewer to be familiar with these before initiating any dialogue with the client, and to convey this information at the outset of the assessment. In fact, an honest discussion of confidentiality may contribute to the validity of the assessment. Research indicates that clients are more likely to disclose personal and potentially critical diagnostic information when confidentiality, and its limits, are clear (Kremer & Gesten, 1998).

Informed consent refers to sufficient disclosure of information about the nature of the assessment so that a competent person can make a voluntary decision to continue (APA, 2002). This is frequently provided both orally and in writing, using clear and understandable language. Informed consent is not only mandatory, but also facilitates the interview process. Clients become actively engaged in the assessment because they are aware of what to expect, the potential risks and benefits, and they agree to accept shared liability and responsibility for the interview (Beahrs & Gutheil, 2001).

Moving from communicating standard information to discussing the client's presenting problems signals a transition to the information collection phase of the interview. Most interviews begin with an open-ended question and then proceed with more direct questions throughout the session to obtain targeted information. Often, the interviewer is interested in hearing, in the client's own words, what led him or her to seek treatment at that time (e.g., "Tell me what brings you to therapy at this time"; Sommers-Flanagan & Sommers-Flanagan, 2009, p. 155). This puts the client at ease, and allows the interviewer to make important behavioral observations, regarding such variables as the client's ability to organize his or her thoughts, tone of voice, energy level, body language, and interpersonal style (Sommers-Flanagan & Sommers-Flanagan, 2009). Although this may be done with varying degrees of formality depending on the type and structure of the interview, in essence, this portion sets the tone for the remainder of the assessment.

## Body

The body of the interview is generally the most variable section, defined by the depth, breadth, and structure of the assessment. It is a process of information gathering, in which hypotheses are formed and refined, and a complete picture of the client is developed. The format of this section is based almost entirely on the type of interview conducted. Some interviews may cover a breadth of psychological disorders, whereas others will focus on a specific area of interest in some depth. For example, the *Structured Clinical Interview for DSM-IV* (SCID-IV; First, Spitzer, Gibbon, & Williams, 2007) is a comprehensive assessment of the most prevalent Axis I disorders, whereas the *Anxiety Disorders Interview Schedule for DSM-IV* (ADIS-IV; Brown, Di Nardo, & Barlow, 1994) assesses in depth the presence and severity of anxiety disorder symptoms, as well as disorders that often occur in the context of anxiety disorders. The body of the interview will also depend on the degree of structure. Structured interviews contain primarily closed questions with specified response options. On the other hand, unstructured interviews often allow the client to describe difficulties in his or her own words. Information regarding the body of the clinical interview is discussed for each interview reviewed later in this chapter.

Throughout the interview, the clinician should be aware of inconsistencies in reported symptoms and behavior. The implicit assumption is that the client and interviewer work together to obtain complete and accurate information. However, some clients may adopt response styles that interfere with this process. For example, a client may overendorse symptoms in an effort to "fake bad," as in malingering, or provide socially desirable responses in order to "fake good" (Rogers, 2001). Interpreting these inconsistencies may be more difficult with unstructured interviews, as they may be an artifact of the question form or sequence (Rogers); however, it is the task of the interviewer to resolve the discrepancies when making diagnostic conclusions and treatment recommendations. Several strategies may be useful, such as using counterbalanced and neutral questions, seeking corroborative data, and using clinical judgment to assess the plausibility of the client self-reports (Rogers, 2001).

## Closing

At the end of the session, the interviewer should reserve time to summarize the main themes of the

assessment, address any questions or concerns, and discuss the next steps. In most jurisdictions, communicating a diagnosis is considered a controlled act requiring a minimum level of professional competence; therefore, when summarizing and organizing reported symptoms, the interviewer should be mindful of relevant legal restrictions. Once the information has been summarized and presented to the client, the client should always have an opportunity to confirm the conclusions. Occasionally, the interviewer may recommend treating a different problem than the client wishes to focus on in treatment. Unless the client is at risk of endangering himself or herself, or someone else, the client is ultimately responsible for determining the course of treatment. Often, the clinician will provide some basic psychoeducation regarding the nature of the client's difficulties as well as treatment options. The interview typically concludes with a clear description of the next steps in the process, such as when and how results and recommendations will be communicated to both the referral source and the client, and resolution of payment, as established at the outset of the session.

## Content of the Interview
### Unstructured Clinical Interviews
Unstructured interviews are used to collect information about client problems and goals, background and personal history, symptoms, level of functioning, and behavioral observations. The significance of each piece of information is weighted by the referral question, and by the confidence that the clinician has in the information obtained. In a crisis mental health care setting, for instance, the interviewer may be particularly interested in behavioral observations, including the client's appearance and emotional state, such as signs of anxiety, agitation, frustration, or anger. Although these pieces of information are important in all assessments, other settings may focus more on other aspects of an individual's symptoms.

Time constraints, coupled with an open-ended question style, produces an interview focused on depth rather than breadth of diagnostic coverage. Although this remains one of the largest criticisms of unstructured interviews because of the potential for missed diagnoses (Zimmerman & Mattia, 1999a), they have also been credited with focusing on the client's primary concerns and thus enhancing rapport (Miller, 2003). The format of the interview is inherently structured to develop rapport.

Using open-ended questions early in the interview then transitioning to questions targeting specific symptoms encourages a feeling of being understood (Beutler & Groth-Marnat, 2005). Moving from less-sensitive to more difficult topics is useful, particularly for clients who are somewhat guarded or unsure of the interview procedure (Beutler & Groth-Marnat). Although the goal of the clinical interview is to obtain information necessary for diagnosis and treatment, a pragmatic yet empathic stance serves to bolster the validity of the assessment outcome.

### Client Problems and Goals
The unstructured interview should begin by defining the client's presenting problems and goals. Allowing the client to describe, in his or her own words, what led him or her to seek treatment at that time orients the clinician to preliminary working hypotheses and suggests how to direct the remaining interview. Additional information is indirectly obtained regarding the client's emotional and cognitive state, degree of insight about one's symptoms, and motivation for treatment. Although some clients may have a high degree of insight into their symptoms and be able to articulate their concerns, others may benefit from a more facilitative approach on the part of the interviewer, using reflective listening and frequent paraphrasing. It is worth noting that many psychological terms have become colloquial, and may not carry the same meaning for a patient as a clinician. For example, many people describe experiencing a "depression," although this often refers to feelings of low mood and may not be accompanied by the additional symptom and duration criteria required for a diagnosis of major depressive disorder. Terms such as "paranoid," "obsession," "compulsion," and "psychotic," also tend to have different meanings when used colloquially versus the way they are defined by mental health professionals. An explorative dialogue is necessary to make a confident diagnosis.

It is useful to ask the client for a summary of his or her concerns at the beginning of the assessment. Most unstructured interviews are conducted in a 50–60-minute session, and a failure to be clear about the client's concerns at the outset could lead to unproductive lines of questioning and inefficient use of limited time. In addition, it may introduce threats to the therapeutic relationship if the clinician has failed to truly understand what the client has expressed.

### Background and Historical Information

Obtaining a complete picture of the individual, including personal and family history, and the development and course of the problems is most easily and accurately accomplished in an unstructured interview than through any other means (Beutler & Groth-Marnat, 2005). Although the interview can only capture the person's functioning at a single moment in time, a thorough personal history collects information about the biological and psychosocial factors affecting the client's current condition. In some cases, establishing a long-standing pattern of behavior is essential for assigning a diagnosis that takes into account the timing of a problem. For example, a personality disorder diagnosis can only be made if symptoms are present beginning in adolescence or early adulthood (APA, 2000). Similarly, a diagnosis of dysthymic disorder can only be assigned after considering the temporal relationship between the symptoms of dysthymic mood and any past major depressive episodes that may have occurred (APA, 2000). Thus, the historical information takes on added significance for certain diagnostic categories.

Typically, information about the individual's social and family history, symptom onset and course, and treatment history are collected. Other common areas of inquiry include educational attainment, employment history, peer and romantic relationships, medical and health history, and patterns of alcohol and drug use. The extent of background information collected and the domains explored will depend on the purpose of the interview. For example, some crisis settings may focus on the course and treatment history of the presenting problem, whereas therapy settings may be more likely to collect a broader personal and family history. Understanding the onset and course of the presenting problem requires information about life events at the time of symptom onset, the frequency and duration of the symptoms, and how the symptoms have changed over time (Beutler & Groth-Marnat, 2005). The course of the disorder should be considered alongside the individual's family and social history, to identify possible contributing factors and consequences of the symptoms.

Treatment history and coping strategies (e.g., noting what has and has not provided symptom relief in the past), provide a clearer picture of the nature of the problem and the client's personality, and are useful in case formulation. Importantly, a pattern of excessive treatment-seeking may be indicative of a tendency toward dependence and low self-efficacy (Beutler & Groth-Marnat, 2005). On the other hand, success in previous treatment may suggest a high degree of motivation to obtain help for one's difficulties (Beutler & Groth-Marnat, 2005). A careful examination of precipitating factors and treatment outcome is recommended before current treatment recommendations are made.

### Behavioral Observations

Behavioral observations are an important part of the clinical interview. During the clinical interview, assessors will typically take note of the client's appearance, behavior, mood and affect, motor activity, and quality of thought and speech. Such observations are made in an unobtrusive manner and provide important information over and above client self-reports. The client's verbal and nonverbal behavior during the assessment can provide corroborating information for reported symptoms, but may also alert the clinician to inconsistencies. For example, a client who reports being deeply depressed yet displays positive affect and normal motor activity may suggest the possibility of low insight or malingering.

The mental status examination (MSE) is a system by which clinicians can categorize their observations. The MSE is used primarily to make inferences about cognitive functioning. Generally, MSEs include the following categories of observations (Sommers-Flanagan & Sommers-Flanagan, 2009):

- Appearance (e.g., grooming, weight)
- Physical movements (e.g., avoidance of eye contact)
- Attitude toward the assessor (e.g., hostile, cooperative)
- Mood and affect (e.g., euphoric, irritable)
- Thought and speech (e.g., flight of ideas, tangential speech)
- Delusions and hallucinations
- Orientation and consciousness (i.e., awareness of who one is, where one is, and what day it is)
- Memory and intelligence (e.g., memory for facts, problem-solving ability)
- Reliability (e.g., vague self-report; inconsistency across multiple assessments), judgment (e.g., impulsive decision-making), and insight (e.g., belief that one's psychological problems are due exclusively to a medical problem)

Behavioral observations are subjective. The clinician is comparing the client's presentation to a prototype that has been developed through clinical experience

to determine if the presentation deviates from the "norm." Therefore, when making diagnostic determinations or reporting to a referral source, specific examples of behavioral observations are critical to support one's clinical impressions. These important pieces of information are also useful for determining suitability for particular treatment modalities. Inappropriate affect may disrupt the group dynamic in group therapy, and a patient who demonstrates low cognitive abilities may not benefit fully from certain types of therapy (Mohlman & Gorman, 2005; Sams, Collins, & Reynolds, 2006).

## Summary

The unstructured interview has several advantages. It provides maximum flexibility for the clinician to formulate questions, develop and test hypotheses, and to establish a diagnosis. One of the primary strengths of this format is that the majority of questions are tailored to the client's presenting problems, creating a more conversational flow, which has been credited with enhancing rapport (Miller, 2003). In addition, administration time is typically shorter than for more structured formats, making unstructured interviews a potentially efficient tool in the assessment process.

Despite these benefits, unstructured interviews have been subject to criticism, primarily because of their inability to produce consistent and accurate diagnoses. The psychometric properties of unstructured interviews are generally unsatisfactory. Research has found that traditional interviews are able to adequately and consistently detect the presence of clinically significant symptoms only about half of the time (Beck, Ward, Mendelson, Mock, & Erbaugh, 1962; Tiemens, VonKorff, & Linn, 1999). Validity and reliability are complicated by the reliance on patient reports and clinician interpretation. There is often little agreement between patient questionnaire data and the information obtained in the interview (Beutler & Groth-Marnat, 2005). In addition, clinical judgment is fallible, subject to subtle and unintentional biases that may color the interview process (Arkes, 1981; Garb, 1998). This may account for the low inter-rater reliability, as two similarly trained clinicians frequently reach different conclusions (Ward et al., 1962).

An extensive literature has explored the phenomenon of underdiagnosis with traditional interviews, resulting in missed diagnoses and potentially inappropriate treatment recommendations (Tiemens, VonKorff, & Linn, 1999; Zimmerman & Mattia, 1999a). Clinicians are often more aware of and comfortable assessing for disorders frequently seen in clinical practice, thus underdiagnosing uncommon disorders (Zimmerman & Mattia, 1999a). Further, it is not uncommon for clinicians to stop after reaching the first diagnosis, thus missing potential comorbidity (Rogers, 2003). This tendency to seek diagnostic information that confirms one's initial clinical impressions is minimized with structured interviews because symptoms are assessed for a range of psychological disorders. It is therefore recommended that unstructured interviews be used to screen clients for subsequent, more thorough, assessments should they be warranted, and to obtain information to supplement and corroborate that obtained from other sources, such as self-report measures, structured interviews, and other informants.

## Structured and Semi-structured Interviews for Assessment of Axis I Disorders
### Overview of Structured and Semi-structured Interviews

Over the years, changes in diagnostic nomenclature have served to reduce the subjectivity of unstructured assessments by incorporating more specific and reliable diagnostic criteria (Rogers, 2001). Imposing a greater degree of structure has naturally led to the development of structured interview formats reflecting the diagnostic categories outlined in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM) and the World Health Organization's (WHO) *International Classification of Diseases* (ICD). Introducing standard questions and response formats has, generally speaking, had the intended effect. Reliability improves as the degree of structure increases, with fully structured interviews resulting in the greatest test–retest and inter-rater reliability (Rogers, 2001; Wood, Garb, Lilienfeld, & Nezworski, 2002). Similarly, structured assessments tend to be characterized by stronger validity than unstructured formats for both Axis I and Axis II diagnoses (Basco et al., 2000; Miller, Dasher, Collins, Griffiths, & Brown, 2001; Widiger, 2002).

The reasons for this may seem obvious. Standardization removes much of the variability introduced by the idiosyncratic nature of unstructured interviews discussed earlier. Ward, Beck, Mendelson, Mock, and Erbaugh (1962) analyzed sources of diagnostic variability in unstructured interviews and determined that most of the variance is introduced by the clinician. *Information variance*, or differences in the amount and type of information collected by the clinician, and *criterion variance*, the

interpretation of that information in making clinical diagnoses, accounted for 95% of the variability in diagnoses between psychiatrists, whereas, only 5% of the variability was due to *patient variance*, or inconsistent presentation on the part of the client. Structured and semi-structured interviews minimize information and criterion variance by standardizing the question wording, coverage, sequencing, and response interpretation uncontrolled for in unstructured interviews. Semi-structured interviews are considered the "gold standard" in psychiatric diagnostic interviewing because of their ability to produce reliable, accurate, and complete diagnoses (Miller, Dasher, Collins, Griffiths, & Brown, 2001; Zimmerman, 2003).

In this section, we review a few of the interviews that are used to assess DSM-IV or ICD-10 psychological disorders. Readers should be aware, however, that revised versions of these interviews will likely be developed once the new versions of these classification systems are published. DSM-5 and ICD-11 are scheduled for release in 2013 and 2015, respectively.

### Diagnostic Interview Schedule

The Diagnostic Interview Schedule (DIS) was one of the first fully structured diagnostic interviews designed to standardize psychological assessment procedures for use in epidemiological research (a review of the evolution of the DIS can be found in Helzer and Robins, 1988). The current version, the DIS-IV (Robins et al., 1995), is oriented around DSM-IV diagnostic criteria (American Psychiatric Association, 2000), assessing a broad range of Axis I disorders, including mood and anxiety disorders, substance use disorders, and, to a lesser extent, disorders first diagnosed in infancy, childhood, and adolescence. A strength of the DIS is that it obtains information regarding age of onset, demographic risk factors, and possible organic etiology of each disorder assessed, as well as cognitive impairment. Initial questions screen for the presence of symptoms, and affirmative responses are followed by additional probes specified by a *Probe Flow Chart*. Questions are read verbatim, and unstructured follow-up questions are not permitted, aside from the additional probe questions provided in the manual. A diagnostic determination is made by a computer scoring system that assigns diagnoses based on reported symptoms and etiology. The high degree of structure also lends itself to computer administration, with versions of the DIS available in computerized formats for use by patients and clinicians.

The highly structured format allows administration by both professionals and trained nonprofessionals, and has produced moderate inter-rater agreement between these groups (Robins, Helzer, Ratcliff, & Seyfried, 1982). However, studies of the validity of the DIS are less encouraging. Concordance between diagnoses made by psychiatrists and the DIS is typically poor (Anthony et al., 1985; Folstein et al., 1985), and a review of several studies indicates that the DIS shows poor concurrent validity with other diagnostic measures (Rogers, 2001). A comprehensive review of psychometric properties of the DIS can be found elsewhere (Rogers, 2001; Summerfeldt & Antony, 2002). The somewhat questionable psychometric properties suggest that the DIS should not be used for clinical diagnosis, but may be useful to screen individuals for subsequent, more comprehensive assessments.

### Diagnostic Interview Schedule for Children

The Diagnostic Interview Schedule for Children (DISC; Costello, Edelbrock, Dulcan, Kalas, & Klaric, 1984), like its adult counterpart, is a fully structured clinical interview designed to assess a broad range of current and lifetime psychiatric disorders. Developed by the National Institute of Mental Health for epidemiological purposes, the most recent version, the DISC-IV, is used in both research and clinical settings (Shaffer, Fisher, Lucas, Dulcan, & Schwab-Stone, 2000). The interview questions closely correspond to both DSM-IV and ICD-10 diagnostic criteria for over 30 diagnoses assessed in six modules, including anxiety disorders, mood disorders, disruptive disorders (e.g., attention-deficit hyperactivity disorder, conduct disorder), substance use disorders, schizophrenia, and miscellaneous disorders (e.g., eating, elimination, and tic disorders). Like the SCID, each module is self-contained and may be skipped if no symptoms are present, without affecting the overall validity of the assessment.

Two parallel versions of the DISC-IV are intended for use with children (DISC-C for children aged 9–17) and parents (DISC-P for parents of children aged 6–17). Both versions follow the same highly structured "stem-and-branching tree" format as other structured interviews, but have shorter sentences and simplified wording to be understandable to both children and adults (Edelbrock, Costello, Dulcan, Kalas, & Conover, 1985). Reliability studies indicate that there is moderate agreement between parent and child scores (Edelbrook et al., 1985); however, the child version has lower test–

retest reliability (Edelbrook et al., 1985; Schwab-Stone, Fisher, Piacentini, Shaffer, Davies, & Briggs, 1993) and sensitivity (Fisher et al., 1993) than does the parent version. Further, test–retest reliabilities are sensitive to age; that is, younger children tend to have lower reliability estimates than do older children (Edelbrook et al., 1985). Therefore, it is recommended that the clinician weight the outcome of the parent version more than the child version when making diagnostic decisions (Rogers, 2001). Nevertheless, reliability studies suggest moderate to excellent overall reliability for current diagnoses (Rogers, 2001). Validity studies indicate that the DISC is best conceptualized as a measure of general impairment, as it has only modest convergent and concurrent validity at the level of individual diagnosis. For a thorough review of the psychometric properties of the DISC, see Rogers (2001).

## Composite International Diagnostic Interview

The Composite International Diagnostic Interview (CIDI; World Health Organization, 1997) was designed primarily for use in cross-cultural epidemiological research, using the DIS as a template while incorporating more culturally diverse items (Robins et al., 1988). The CIDI has undergone several revisions; the most recent version, the CIDI 3.0 (Kessler & Üstün, 2004), directly corresponds with both DSM-IV and ICD-10 diagnostic criteria. Like the DIS, the CIDI is a fully structured diagnostic interview suitable for administration by both professionals and trained lay persons. Although the question wording has changed slightly for some items, the CIDI retains every item from the DIS and the identical response format.

Although the DIS was once the most widely used assessment tool in epidemiological research, the CIDI has been the most frequently used instrument for this purpose for over a decade because of its greater applicability across cultures, compared to the DIS. To illustrate, the CIDI has been translated into 32 languages (Kobak, Skodol, & Bender, 2008) and has undergone validation studies for many of these translations. In addition to research applications, the CIDI-Primary Health Care Version (CIDI-PHC) can be used as a diagnostic tool in clinical practice, although this application is less common. Other versions exist for self- or clinician administration, 12-month and lifetime assessment, and paper-and-pencil and computer administration.

Most research regarding the psychometric properties of the CIDI has been conducted for version 2.1 or earlier. Generally, reliability statistics are impressive, with inter-rater reliability estimates of .90 or greater, and good to excellent test–retest reliability for most diagnoses (Andrews & Peters, 1998). However, many reliability and validity studies are confounded by using the DIS, which comprises much of the CIDI, as a comparison measure (Rogers, 2001). Nevertheless, recent studies have found high concurrent validity of CIDI 3.0 and SCID-IV diagnoses, despite the somewhat more conservative prevalence estimates detected by the CIDI (Haro et al., 2006; Kessler et al., 2006). For a comprehensive and balanced review of the psychometric properties of the CIDI see Andrews and Peters (1998), and Rogers (2001).

## Structured Clinical Interview for DSM-IV

The SCID (First, Spitzer, Gibbon, & Williams, 2007) is a semi-structured diagnostic interview that assesses a broad range of DSM-IV Axis I disorders. To reflect changes to the DSM, the SCID has undergone several revisions, beginning with the first edition in 1985 for the DSM-III to the DSM-IV version first published in 1996, and most recently updated in 2007. Importantly, it has remained true to the DSM's multiaxial assessment system, collecting information about the historical, medical, psychosocial, and environmental factors possibly contributing to the individual's presenting problems.

There are several versions of the SCID-IV, each with differing breadth and depth of inquiry. The SCID-I (First, Spitzer, Gibbon, & Williams, 2007) is intended for a research audience and provides the broadest coverage of Axis I disorders. The SCID-CV (First, Spitzer, Gibbon, & Williams, 1996) is a briefer version, intended for clinical settings, that does not collect the depth of information in the research version and eliminates questions regarding course specifiers unless required for a diagnosis (e.g., mood disorders). Further, the SCID-CV does not assess disorders rarely seen in clinical practice, such as minor depressive disorder, acute stress disorder, and binge eating disorder. Separate tests designed to supplement the SCID have been developed to assess dissociative disorders (SCID-D; Steinberg, 1994) and Axis II personality disorders (SCID-II; First, Gibbon, Spitzer, Williams, & Benjamin, 1997) independently.

The format of the SCID also parallels that of the DSM-IV. The test manual is organized into modules according to symptom clusters and disorders, allowing the interviewer to skip sections that are not relevant for a particular client. An optional

screening module early in the interview identifies the presence of symptoms requiring further investigation, and suggests which modules may be omitted. This saves time in administration, as the clinician is not unnecessarily querying symptoms of little relevance. However, this may have the unintended consequence of failing to alert the clinician to subtle or atypical symptoms, resulting in missed diagnoses (Rogers, 2001). Anticipating such a problem, the SCID also includes skip-out rules when assessing for each disorder, so that the interviewer may proceed to the next module if the client does not endorse symptoms. Thus, the SCID can be administered in its entirety, while still eliminating unnecessary questioning.

The SCID is organized into a three-column format, with the left column containing the questions, the middle column containing the corresponding diagnostic criteria, and the right column containing the response options and branching rules. The questions are read verbatim, with probes provided to clarify the client's responses. The interviewer is permitted to generate additional probes to elicit adequate information and relevant examples. Responses are recorded on a 3-point categorical scale based on the diagnostic criteria, where 1 indicates the symptom is absent, 2 indicates that the symptom is present at a subthreshold level, and 3 indicates the symptom is present. If criteria are met for a particular disorder, a severity rating may be provided, based on the clinical judgment of the interviewer.

Generally, the SCID has demonstrated adequate psychometric properties with clinical samples. Space constraints do not allow us to review the extent of research available regarding the reliability and validity of the SCID; for a comprehensive review of the literature see Rogers (2001). Rogers (2001) reported moderately high to superb inter-rater reliability for current diagnoses, although studies have shown that reliability statistics vary by disorder. For example, in the largest and most thorough reliability study to date (Williams et al., 1992), test–retest reliability of the SCID-I for DSM-III was found to be high for bulimia but considerably lower for dysthymia, and there was substantial site-to-site variation (κ ranged from .37 to .82 for major depressive disorder). Similarly, studies of the SCID-I for DSM-IV indicate that reliability statistics vary by disorder, with the highest test–retest and inter-rater reliability for alcohol and substance use disorders, and the lowest reliability estimates for dysthymic disorder and generalized anxiety disorder. In addition, reliability

statistics have tended to be much lower in nonclinical samples (Zanarini et al., 2000). Studies of the validity of the SCID have largely been limited to concurrent validity, and have rarely assessed criterion-related validity because of its high concordance with the DSM. The SCID has generally demonstrated moderate levels of concurrent validity for current diagnoses with the CIDI (Haro et al., 2006) and the *Mini International Neuropsychiatric Interview* (MINI; Sheehan et al., 1997). Compared to disorder-specific measures, the SCID has demonstrated adequate convergent validity for PTSD, depression, and substance abuse, but is less than impressive for panic disorder and psychotic disorders (Rogers, 2001).

In summary, the SCID is a commonly used instrument in both research and clinical settings and is designed to assess for a range of Axis I and Axis II disorders. After adequate training, many clinicians are comfortable with the administration because of the close resemblance to the DSM-IV. Finally, the adequate psychometric properties of the SCID ensure that a skilled clinician can be reasonably confident in the validity of his or her assessment.

### Anxiety Disorders Interview Schedule for DSM-IV

The Anxiety Disorders Interview Schedule for DSM-IV (ADIS-IV; Brown et al., 1994) provides a detailed assessment of symptoms for DSM-IV anxiety disorders and also includes sections for the diagnosis of mood, substance use, psychotic, and somatoform disorders. For each of the anxiety disorders assessed (panic disorder, social phobia, specific phobias, obsessive-compulsive disorder, post-traumatic stress disorder, and generalized anxiety disorder), information is obtained regarding the specific symptom presentation, and the intensity of fear and avoidance, as well as age of onset and possible etiology. Like other semi-structured interviews, the ADIS-IV is designed to be administered only by trained professionals and is suitable for use in both research and clinical settings. The flexibility of the semi-structured interview permits the clinician to ask unstructured follow-up questions and to probe for relevant examples, where appropriate, to aid with diagnosis and treatment planning. The lifetime version (ADIS-IV-L; Di Nardo, Brown, & Barlow, 1994) expands on the standard version to query about both lifetime and current diagnoses, as well as symptom course. An adaptation of the ADIS-IV is also available for children (ADIS-IV-C) and their parents (ADIS-IV-P; Silverman & Albano, 1996).

Most studies on the reliability of the ADIS have been conducted for earlier versions. In a large-scale study assessing the reliability of the ADIS-IV, reliability was found to be in the range of good to excellent for all disorders except dysthymic disorder (Brown, Di Nardo, Lehman, & Campbell, 2001). Although few studies have evaluated the validity of the ADIS, Rogers (2001) concluded, based on limited available evidence, that convergent validity is in the moderate range. The child and parent versions of the ADIS-IV have demonstrated excellent interrater reliability (Lyneham, Abbott, & Rapee, 2007), test–retest reliability (Silverman, Saavedra, & Pina, 2001), and strong concurrent validity at the disorder level (Wood, Piacentini, Bergman, McCracken, & Barrios, 2002). It should be noted that most studies on the properties of the ADIS-IV and ADIS-C/P have found lower reliability estimates for generalized anxiety disorder (GAD), possibly because of the high diagnostic overlap with other disorders (Brown et al., 2001; Wood et al., 2002).

### Mini-International Neuropsychiatric Interview

The Mini-International Neuropsychiatric Interview (MINI; Sheehan et al., 1997) is a brief semi-structured diagnostic interview for the assessment of DSM-IV and ICD-10 disorders. Although designed for research use, the MINI is also used as a screening measure in clinical contexts, largely because of its relatively brief administration time (15–20 minutes) and broad diagnostic coverage. It is designed to assess the current, but not lifetime, diagnosis of 15 Axis I disorders, including anxiety, mood, substance use, eating, and psychotic disorders, and antisocial personality disorder. In addition to the original MINI, there are three other versions: the MINI-Screen, an abbreviated version of the original for use in primary care settings; the MINI-Plus, to include assessment of lifetime diagnoses; and the MINI-Kid, for use with children. The MINI has been translated into 43 languages, and has demonstrated impressive reliability and validity, making it an ideal tool for cross-cultural epidemiological research. A review of the development and psychometric properties of the MINI can be found in Sheehan et al. (1998) and Lecrubier et al. (1997).

### Disorder-specific Interviews

The interviews described in the previous sections generally provide broad diagnostic coverage for situations in which the nature of the presenting problem is unknown, or to obtain information of interest for researchers. In many cases, the goal of the clinical interview is to obtain detailed information about the complexities of a particular disorder. Disorder-specific measures also vary in their depth and breadth of coverage; however, they typically focus on a single disorder or domain. The reader is referred to Table 12.1 for examples of measures that are commonly used in both research and clinical settings. Detailed information to help determine which disorder-specific interview may be most appropriate for a particular application may be found elsewhere (e.g., Antony & Barlow, 2002; Hunsley & Mash, 2008).

### Structured and Semi-structured Interviews for Assessment of Axis II Disorders

Personality disorders are rarely the primary reason that a person is seen for an assessment; rather, individuals are likely to seek treatment for Axis I conditions. Personality disorders are characterized by maladaptive and inflexible ways of thinking, feeling, and behaving, but it is precisely these features that treatment aims to change. Thus, if a personality disorder is present and undetected prior to initiating treatment, it may have the unintended consequence of interfering with the course of treatment, and often with a successful outcome (Widiger, 2002). However, personality disorders are modifiable if appropriately detected and targeted for treatment. Several inventories are available in the form of self-report personality questionnaires, such as the Minnesota Multiphasic Personality Inventory (MMPI-2; Colligan, Morey, & Offord, 1994) and the NEO PI-R (Costa & McCrae, 1992), which do not provide a targeted assessment of personality disorders per se, but provide response profiles characteristic of personality disorders in the scoring manual. Self-report questionnaires and unstructured interviews alone often provide inaccurate and unreliable diagnoses, whereas structured and semi-structured interviews have been found to be the most efficient and accurate assessment tools for Axis II disorders (Widiger & Samuel, 2005). Unfortunately, unstructured interviews are the norm in clinical practice (Zimmerman & Mattia, 1999b). Below is a brief review of three commonly used clinical interviews for Axis II personality disorders: the Structured Interview for DSM-IV Personality Disorders (SIDP-IV; Pfohl, Blum, & Zimmerman, 1997), the International Personality Disorder Examination (IPDE; Loranger, 1999),

**Table 12.1  Interview-based Symptom Measures**

| | Name of measure | What it assesses | Administration time | Psychometric properties |
|---|---|---|---|---|
| Anxiety Disorders | Yale-Brown Obsessive Compulsive Scale (Y-BOCS; Goodman et al., 1989a, 1989b. Y-BOCS-II; Goodman, Rasmussen, Price, & Storch, 2006; Storch et al., 2010a, 2010b) | Severity and nature of OCD symptoms | 45 minutes | Good to excellent inter-rater reliability, internal consistency, and test-retest reliability; limited information regarding test validity, but preliminary information indicates adequate validity |
| | Liebowitz Social Anxiety Scale (LSAS; Liebowitz, 1987) | Measures fear and avoidance of social and performance situations | 10 minutes | Demonstrated adequate psychometric properties |
| | Clinician-Administered PTSD Scale for DSM-IV (CAPS; Blake, Weathers, Nagy, Kaloupek, Charney, & Keane, 1998) | Current and lifetime PTSD symptoms | 45–60 minutes | Good to excellent psychometric properties |
| Depression | Hamilton Rating Scale for Depression (HRSD; Hamilton, 1960, 1967) | Severity of depressive symptoms | 30+ minutes | Good inter-rater reliability and moderate internal consistency; good convergent validity but inconclusive concurrent and discriminant validity |
| | Brief Psychiatric Rating Scale (BPRS; Overall & Gorham, 1962) | Presence and severity of Schizophrenia and Mood Disorder symptoms | 10–40 minutes | High inter-rater reliability, and concurrent and construct validity |
| Substance Use Disorders | Comprehensive Drinker Profile (CDP; Miller & Marlatt, 1984) | Extent of substance use, related psychosocial problems, and motivation for change | 120 minutes | Excellent inter-rater reliability, and good predictive and convergent validity; moderate agreement between interviewer and client reports |
| | Addiction Severity Index (ASI; McLellan, Luborsky, Woody, & O'Brien, 1980) | Overview of problems related to substance use | 45 minutes | Generally excellent reliability estimates; modest convergent validity |
| Eating Disorders | Eating Disorders Examination (EDE; Fairburn & Cooper, 1993) | Presence and frequency of bulimia symptoms | 30–60 minutes | Adequate internal consistency and excellent inter-rater reliability; good construct and discriminant validity; distinguishes people with bulimia from people with other eating disorders. Considered the gold standard for ED diagnosis |

Table 12.1  Interview-based Symptom Measures    (*Cont'd*)

| | Name of measure | What it assesses | Administration time | Psychometric properties |
|---|---|---|---|---|
| Eating Disorders (*Cont'd*) | Interview for the Diagnosis of Eating Disorders-IV (IDED-IV; Kutlesic, Williamson, Gleaves, Barbin, & Murphy-Eberenz, 1998) | Initial assessment of severity and frequency of eating disorder symptoms | 30–90 minutes | Excellent reliability and good convergent, content, and discriminant validity |
| Schizophrenia | BPRS most commonly used | | | |
| | Comprehensive Assessment of Symptoms and History (CASH; Andreason, 1987) | Positive and negative symptoms of schizophrenia | 120 minutes | Adequate reliability estimates; preliminary validity data are promising |

and the Structured Clinical Interview for DSM-IV Axis II Personality Disorders (SCID-II; First et al., 1997). A review of all interview measures is beyond the scope of this chapter; for a thorough review of measures and psychometric data, see Rogers (2001). For recommendations regarding selecting an appropriate measure, see Widiger (2002).

### *Structured Interview for DSM-IV Personality Disorders*

The SIDP-IV (Pfohl, Blum, & Zimmerman, 1997) is a clinician-administered semi-structured diagnostic interview whose items correspond closely with DSM-IV criteria. The questions are organized by ten areas of an individual's life, (e.g., interests and activities, work style, relationships, emotions, and social perception), rather than diagnostic categories; therefore, face validity of the items is low, minimizing the possibility of being confounded by particular response sets. Further, the organization of the questions progresses from less threatening to more intrusive, which creates a more conversational flow and is useful in developing rapport. An optional third-party interview is available to corroborate the information obtained in the patient version of the SIDP-IV, if the clinician deems it necessary. Possibly because of a lack of insight characteristic of personality disorders, or because many do not see their symptoms as distressing or impairing, the informant interview has been found to increase the accuracy of clinical diagnoses (Berstein et al., 1997).

The SIDP-IV has received good empirical support, with several studies reporting reliability and validity in the good to high range (Rogers, 2001). Rogers concludes that "the SIDP is an excellent Axis II

interview that should be strongly considered in a wide range of clinical settings" (p. 383). Despite the lengthy administration time (60–90 minutes), the strong psychometric properties and suitability for use with patients presenting with both Axis I and Axis II disorders make this is an ideal instrument for use in clinical practice.

### *International Personality Disorders Examination*

The IPDE (Loranger, 1999) is a clinician-administered semi-structured interview that uses both dimensional and categorical ratings to provide information about the presence and severity of personality disorders. It is unique among personality disorder assessments in that it includes a self-administered paper-and-pencil screening questionnaire to detect the possible presence of a personality disorder before proceeding with the clinical interview. The IPDE is a modification of its predecessor, the PDE (Loranger, 1988), to include a module for assessment of ICD-10 personality disorders, as well as the DSM-IV. It should be noted that some questions related to DSM-IV criteria are used to assess for ICD-10 diagnoses despite sometimes substantial differences in the diagnostic criteria between the classification systems. However, the strong psychometric properties of the IPDE, and the cross-national validation, suggest that it is an acceptable standardized diagnostic tool for use worldwide.

Like the SIDP-IV, questions on the IPDE are organized according to life domains and can be used with both patient and informant interviews. However, unlike the SIDP-IV, the IPDE items are relatively transparent and therefore vulnerable to distortion in

client reports, somewhat limiting its validity (Boyle, 1998). This appears to be only a minor consideration, as studies have demonstrated that the reliability and validity of the IPDE are generally moderate to excellent (Rogers, 2001).

### Structured Clinical Interview for DSM-IV Personality Disorders

The SCID-II (First et al., 1997) is a semi-structured interview designed to be used as a companion to the SCID-I. Items are organized by diagnostic modules, rather than life domains (as in other personality disorder interviews) for all ten DSM-IV Axis II personality disorders, as well as depressive personality disorder, passive-aggressive personality disorder, and personality disorder not otherwise specified. The response format is very similar to that of the SCID-I in that a response of 1 indicates the symptom is absent, a score of 2 refers to a symptom that is present at a subthreshold level, and a score of 3 indicates the symptom is present. Its similarity to the SCID-I increases the ease of administration. In addition, a relatively short administration time (30 minutes) makes this a practical instrument for use in clinical settings. Unlike the SCID-I, there are no skip-out rules or branching options; however, the stand-alone modules can be administered independently without impacting the validity of the assessment. Importantly, it also asks the client to provide several examples when endorsing items because symptoms of personality disorders are, by definition, present in many areas of an individual's life.

The SCID-II has demonstrated adequate reliability and validity for most personality disorders (First & Gibbon, 2004; Maffei et al., 1997). The validity of the SCID-II, because of its close adherence to the DSM-IV criteria, is complicated by the questioned validity of personality disorder diagnoses (Bornstein, 1998; Farmer, 2000). This may, in part, reflect a failure to meet the impairment and distress criteria for some personality disorders, particularly histrionic and obsessive-compulsive personality disorders (Ryder, Costa, & Bagby, 2007). Nonetheless, it has been recommended for use in clinical practice because of its ease of use and its acceptable empirical support (Widiger, 2002; Widiger & Samuel, 2005). Importantly, diagnostic accuracy increases substantially when self-report questionnaires are used in combination with semi-structured interviews, with unstructured interviews contributing little to the diagnosis (Widiger & Samuel, 2005; Zimmerman & Mattia, 1999b).

### Summary

Ultimately, structured and semi-structured interviews rely on client self-report; therefore, their validity rests, in part, on the degree of clients' insight and self-disclosure. This may be particularly relevant for conditions that are characterized by low insight regarding the presence of symptoms and degree of impairment, such as bipolar disorder and schizophrenia (Eaton, Neufeld, Chen, & Cai, 2000). In addition, people may intentionally misrepresent their symptoms for purposes of malingering or to appear less impaired. However, the bulk of empirical evidence suggests that structured interviews are superior to both self-report and unstructured interviews in the assessment of both Axis I and Axis II disorders. Although the reliability of an assessment interview may increase as the degree of structure increases, semi-structured interviews have been considered the "gold standard" in clinical interviewing because of their typically strong psychometric properties and comprehensiveness, and their ability to facilitate rapport with the client. A thorough assessment is the first step in the treatment process, and provides the basis for case formulation and treatment planning.

## Assessing Suicide Risk

Client suicidality can be one of the most stressful and intimidating experiences for health professionals, particularly for beginning or inexperienced clinicians and in cases where the client is not known to the clinician or interviewer (e.g., as in the case of an independent assessment). In one study, approximately 19% of psychology interns reported that, during their clinical training, they had a client who attempted suicide, and 11% reported that they had a client who completed suicide (Kleespies, Penk, & Forsyth, 1993). In a study on stress and clinical work, suicide attempts and expressions of suicidality were among the top three stressful client behaviors reported by psychology interns, clinical psychologists, and counselors (Rodolfa, Kraft, & Reilley, 1988). The majority of clinical psychologists actually receive minimal instruction in suicide risk assessment during their training (Dexter-Mazza & Freeman, 2003; Knox, Burkard, Jackson, Schaack, & Hess, 2006), which likely contributes to clinicians' discomfort with this form of clinical interviewing. In the following paragraphs, risk and protective factors for suicide will be described, and this will be followed with an overview of recommended components of suicide risk assessment.

Clinicians and assessors are advised to be highly familiar with the demographic, clinical, and behavioral risk factors for suicidal ideation (i.e., wanting or wishing to be dead), planning, attempt, and completion, as the need to assess for these could arise at any time (Dexter-Mazza & Korslund, 2007). The WHO World Mental Health Survey Initiative has provided data on the risk factors for suicide in 17 countries (Nock et al., 2008). In terms of demographic factors, the findings suggest that being female, being younger, being unmarried, and having fewer years of formal education are all risk factors for suicidal ideation, planning, and attempt. In a recent review, Paris (2006) noted that the profiles of suicide attempters and suicide completers are considerably different, with suicide completers (as opposed to suicide attempters) tending to be male, older, and to use means that are more lethal. In terms of clinical variables, the findings of the WHO study indicate that a diagnosis of a DSM-IV impulse control disorder or mood disorder is also associated with elevated risk of suicidal behavior. In the case of mood disorder, the risk is particularly elevated when it is characterized by anhedonia, hopelessness, or neurovegetative symptoms that are severe, or when psychotic symptoms are present (Dexter-Mazza & Korslund, 2007). The WHO study also revealed that a diagnosis of an anxiety disorder or substance use disorder is associated with an elevated risk of suicidal behavior. In terms of behavioral indicators of suicide risk, the WHO study findings indicate that, among individuals who report suicide ideation, the likelihood of developing a suicide plan and attempting suicide are highest within the first year of ideation onset (Nock et al., 2008).

Dexter-Mazza and Korslund (2007) also note that a history of suicide attempts, in particular attempts that are more serious as defined by clear intent or medically-serious outcomes, also confers risk for suicide. A family history of suicidal behavior has also been shown to be a predictor of suicide; however, it is not known whether this risk is transmitted biologically or whether it is transmitted indirectly, via modeling (Dexter-Mazza & Korslund, 2007). Finally, a diagnosis of schizophrenia is associated with increased risk of suicide, with the risk being highest at the time individuals are first diagnosed and in the period following initial hospitalization (Dexter-Mazza & Korslund, 2007).

In addition to risk factors, the clinician must also inquire about *protective factors*, that is, factors that prevent an individual from considering suicide (Rutter, Freedenthal, & Osman, 2008), as the estimate of suicide risk is determined by a balance of risk factors (particularly the behavioral indicators) and protective factors, and not solely by the presence of risk factors. Examples of protective factors include having loved ones to whom the client feels responsible (e.g., family, spouse, children, and pets), as well as other social supports that are important to the client. However, it should be noted that data from a large-scale epidemiological study (Borges, Angst, Nock, Ruscio, & Kessler, 2008) indicate that, although the presence of young children in the home is associated with a reduced risk of suicide attempt, it has been, on the other hand, linked with *increased* risk of ideation among individuals who engage in suicide ideation, which suggests that stress is an important factor for clinicians to assess and monitor (Borges et al., 2008). A high level of self-efficacy and an expression of hope for the future have also been identified as protective factors (Dexter-Mazza & Korslund, 2007). Some clients also report that they would not consider suicide as an option because it is proscribed within their religion or culture. The reader is directed to Dexter-Mazza and Korslund (2007) for additional information on risk and protective factors for suicide.

A suicide risk assessment allows the clinician to assess the *possibility* (i.e., risk) of suicide; however, it is important to note that it cannot be used to *predict* whether a specific individual will actually carry out the act (Dexter-Mazza & Korslund, 2007). The prediction of who will and will not complete suicide is made complicated by the fact that the majority of individuals with suicidal ideation do not attempt suicide and, in turn, only a minority of attempters complete suicide (Paris, 2006).

As noted earlier, the clinician uses information about risk and protective factors derived from the empirical and clinical literature to arrive at a determination of a client's estimated risk for suicide. As such, the suicide risk assessment should contain questions that elicit information about both types of factors. Dexter-Mazza and Korslund (2007) and Shea (2004) provide examples of key questions that should be asked to assess suicide potential. The interviewer must gather information about (a) demographic and clinical factors that place the client in a high-risk or low-risk category for suicidal behavior (as discussed earlier), (b) the client's history of intentional self-harm and suicide attempts, (c) current behavioral indicators of imminent suicide, and (d) factors that could dissuade the client from considering suicide.

Asking about past instances of self-harm and suicidal behavior will enable the clinician to gain an understanding of the function of these behaviors. Clients should be asked about events or factors that precipitated episodes of self-harm and/or suicidal behavior; the means used to engage in the behaviors, including how they were obtained (Dexter-Mazza & Korslund, 2007; p. 104); the extent to which the behavior was planned; the client's feelings at the time he or she was engaging in the behaviors; and the desired outcome (e.g., relief) (Dexter-Mazza & Korslund, 2007).

In terms of behavioral indicators, there are key questions that clinicians and interviewers must ask to assess *imminent* risk of suicidal behavior. Determining the imminence of suicide potential is critical, as there is an ethical and legal obligation to take steps to reduce imminent risk when it is identified (Sommers-Flanagan & Sommers-Flanagan, 2009). Once it has been established that the client is experiencing suicidal ideation, the clinician or interviewer must ask the client whether he or she has a plan for how the suicide might be completed (Dexter-Mazza & Korslund, 2007). If the client indicates that he or she has a plan, the means with which the client intends to execute the plan and the client's access to those means need to be assessed. The clinician should also pay attention to and assess for indicators that the client is preparing to attempt suicide (e.g., giving away of possessions; preparation of a will). It is important for the clinician to elicit reasons for living. A critical part of suicide risk assessment involves helping the client to develop a "crisis plan" in the event that she or he experiences the urge to act on suicidal ideation (Dexter-Mazza & Korslund, 2007).

Many health professionals report being intimidated by suicide risk assessment because they are afraid that asking questions about suicide might inadvertently "plant the seed of suicide" in a vulnerable individual who is not currently suicidal (Pearson, Stanley, King, & Fisher, 2001). Dexter-Mazza and Korslund (2007) note that there is no evidence to indicate that client suicidality increases after a suicide risk assessment; on the contrary, such an assessment may actually disencumber clients of their private thoughts and feelings about suicide (Dexter-Mazza & Korslund, 2007).

Finally, it should be noted that, for a number of reasons (e.g., embarrassment, fear that disclosure of ideation will result in hospitalization), clients may not readily communicate their suicidal thoughts to the clinician or interviewer (Shea, 2004). Writings on suicide risk assessment often focus on strategies for assessing suicidal *intent*; however, there is not sufficient discussion of strategies for eliciting suicidal *ideation*, even though ideation and intent go hand in hand. The reader is referred to Shea (2004) for a detailed description of the *Chronological Assessment of Suicide Events* (CASE), an interview designed to assess suicidal ideations, intent, and behavior.

## Interviewing: Strategies and Skills
### Interviewer Bias
Human information processing is fallible and largely heuristic; as such, clinicians must be aware of thinking errors (i.e., cognitive biases) that influence their clinical decision-making. With reference to clinical psychologists, Chapman and Chapman (1982) noted that "clinicians are subject to the same illusions as everyone else" and suggested that direct training in cognitive heuristics and biases should be a requirement for graduate students in clinical psychology. Garb and Grove (2005) stated that the ability to identify and safeguard against biases does not come with clinical experience; but rather, with training. In a recent survey of 200 American Psychological Association (APA)-accredited graduate programs in clinical psychology, Harding (2007) found that, although 79% of programs offered at least one course with a section on clinical judgment and decision-making only *one* program offered an entire course on the topic. It appears that although psychologists agree that acquiring skills in clinical decision-making is important, formal training in clinical decision-making is not explicitly built into graduate programs in clinical psychology.

*Representativeness heuristic*, *availability heuristic*, *confirmation bias,* and *illusory correlations* are a few examples of cognitive heuristics that have been shown to affect medical decision-making and may also be the same cognitive processes that promote biases in clinical judgment in a mental health context (Harding, 2007). In the following paragraphs, we will discuss ways in which these heuristics may affect clinical interviewing, diagnostic impressions, and case formulation.

Kahneman and Tversky (1972) defined representativeness as a cognitive error whereby an event is judged to be "similar in essential properties to its parent population." Judgment by representativeness can influence judgments that are made about individuals. If an individual appears to fit some sort of larger category, there is an increased chance that the individual will be viewed as a member of that category. In the "Tom W." problem popularized by

Kahneman and Tversky (1973), a man is described as highly intelligent, lacking in creativity, having a need for order, having a writing style that is "dull and mechanical," and having little sympathy for, and a lack of interest in interacting with, others. When respondents are presented with this description and are asked to indicate his occupation, the majority report that Tom W. is most likely an engineering student and that he is least likely to be a student in social work or the social sciences, even if the objective likelihood is higher that he would be a student in social work or the social sciences. Garb (1998) notes that in a clinical context, representativeness can affect the way in which clinicians diagnose psychological conditions. Specifically, it is not uncommon for clinicians to compare clients to some prototype or exemplar when formulating a diagnostic impression (Garb, 1998). There are risks in making clinical judgments based on representativeness. If the clinician is relying on his or her personal experience with past clients who have features that are similar to those of the individual being assessed, this would constitute a comparison to exemplars who may or may not be representative of the population of interest. In other words, the clinician may be drawing on a limited "sample size" to inform his or her diagnoses. If, however, the client being assessed is being compared to a prototype (i.e., a theoretical standard; Garb, 1998), this may not be as problematic, unless the validity of the prototype can be called into question. If the prototype is invalid, the findings of a diagnostic interview may also be invalid.

Dumont (1993) notes that a clinician's diagnostic impression and case formulation is influenced, in part, by the information he or she can remember after the interview; in other words, information that is *available*. The ease with which one calls up information from memory depends on a number of factors. The vividness or salience of the information (Garb, 1998) and the mood that one is in when listening and processing the information (Dumont, 1993) are both factors that influence what one is able to recall.

Clinical interviewers must also be attentive to *confirmation bias.* Clinicians may enter the assessment with a working hypothesis of the nature of a client's difficulties (based on the referral question or a brief review of a psychological record, for example), which may lead them to inadvertently structure the interview in a manner that confirms their initial hypothesis. As a result, interviewers may be inclined to arrive at diagnostic impressions prematurely, before

all the information has been gathered (Dumont, 1993). For example, if an individual is having difficulty returning to work following a serious industrial accident, it should not be readily assumed that the individual has post-traumatic stress disorder. Meehl (1960) reported that clinical impressions that are derived from 2 to 4 hours of clinical interviewing tend to remain unrevised over the course of treatment. Furthermore, once an impression has been formulated, clinicians tend to perseverate with it, even when disconfirming information is made available to them (Dumont, 1993). Gilovich (1993) notes that, generally, when individuals are presented with disconfirming information, they do not ignore it; but rather, they "shape" the information and incorporate it into their existing clinical conceptualization ("theory salvaging"; Dumont, 1993).

Clinicians' thinking is also susceptible to covariation bias, known also as *illusory correlation*. Humans are "pattern detectors"; as such, we often attempt to draw causal connections between events, even when none exists (Dumont, 1993). Peterson and Beach (1967) and others (e.g., Gilovich, 1993) have discussed problems associated with the "present-present" bias. When individuals are presented with data in a $2 \times 2$ contingency table crossing psychological condition (present-absent) with a putative antecedent (present-absent) and are asked to determine whether there is an association between the two, individuals will tend to concentrate on data in the present-present cell of the table, while ignoring data in the other three cells. McNally (2003), for example, pointed out that the perceived link between sexual abuse in childhood and dissociative disorders in adulthood could be attributed to the present-present bias. A considerable number of individuals with recurrent dissociative experiences may also report a history of childhood sexual abuse; however, this finding cannot be interpreted without information about the number of individuals who report having recurrent dissociative experiences, but *do not* have a history of childhood sexual abuse; such cases may represent the majority. Likewise, the number of individuals with a history of childhood sexual abuse but who *do not* have dissociative experiences may exceed the number of individuals in whom both are present.

Garb (1998) provides a number of suggestions for minimizing the impact of cognitive biases on clinical decision-making. One way by which clinicians can increase the accuracy of their judgments is by actively considering *alternative explanations* for behavior. Garb also recommends that clinicians

should document their observations and clients' reports, and review their notes to reduce reliance on their memory, as memory is fallible and susceptible to distortion.

### Attending

Sommers-Flanagan and Sommers-Flanagan (2009) note that the majority of clinicians, regardless of their clinical orientation, agree that learning how to attend in session is an essential clinical skill. Attending behavior is mainly nonverbal and includes eye contact, body language, and vocalizations.

A considerable amount of information can be gleaned from an individual's nonverbal communication. The following are generally considered to be *positive* attending behaviors (Sommers-Flanagan & Sommers-Flanagan, 2009): leaning slightly toward the client when speaking with or listening to the client; maintaining a relaxed but "alert" posture; keeping hand gestures to a minimum; sitting at a distance of an arm's length from the client; arranging the furniture so that there are no physical barriers (e.g., a desk) between the clinician and the client; and maintaining eye contact with the client.

Clinicians should also be aware of *negative* attending behavior. Body language that may communicate defensiveness (e.g., sitting with arms folded across the chest) or lack of interest (e.g., noticeable and repeated checking of the time) should be avoided. Making too little or too much eye contact can be off-putting. When used excessively, positive attending behaviors can come to be perceived by the client as bothersome or even offensive. For example, use of head nods and "uh huh" statements, although well-intentioned, may be perceived as irritating if they are used excessively. *Selective* use of particular nonverbal behaviors can also have an influence on what the client chooses to discuss in session. If the clinician displays considerable interest (e.g., by leaning forward, nodding frequently) when the discussion turns to a particular topic, this may inadvertently lead a client to stop talking about subjects or problems that he or she perceives to not be of interest to the clinician (Sommers-Flanagan & Sommers-Flanagan, 2009).

### Asking Questions

The clinical interview should not come across as an interrogation; however, as Sommers-Flanagan and Sommers-Flanagan (2009) note, there are times when the interviewer does take on the role of investigator. The particular manner in which questions are asked can have an important impact on the quality and quantity of information that the interviewer acquires during the interview.

Sommers-Flanagan and Sommers-Flanagan (2009) describe five types of questions: open, closed, swing, implied (also known as indirect), and projective.

*Open questions* "are designed to facilitate verbal output" (Sommers-Flanagan & Sommers-Flanagan, 2009, p. 84). For example, questions beginning with *how* foster responses that extend beyond one-word responses. Sommers-Flanagan and Sommers-Flanagan (2009) advise clinicians to be judicious in their use of *why* questions, as these can be experienced by clients as critical and attacking, particularly when rapport has not been established (e.g., "Why haven't you returned to work?"; "Why did you drop out of college?").

*Closed questions*, commonly used in diagnostic interviews, can be responded to with a "yes" or "no" answer (e.g., "Do you experience difficulty bringing your worry under control?"). Questions beginning with *who* (e.g., "Who assists you with activities around the house?), *where* ("Where were you when you experienced your first panic attack?"), or *when* ("When did you first notice that you were having problems managing your anxiety?") are also examples of closed ended questions. Other examples include *do* questions ("Do you become anxious in many social situations, or only in specific ones?") and *are* questions ("Are you having difficulty concentrating?"). Closed questions are easier to formulate than are open-ended questions, which might be why it is not uncommon for beginner interviewers to inadvertently use closed questions where there is the potential to transform them into open questions.

*Swing questions* begin with *could* (e.g., "Could you tell me about your worst panic attack?"; "Could you tell me what it was like to assert yourself to your co-worker?"). Swing questions appear to elicit either a yes or a no response, but actually draw elaborate responses and facilitate discussion. The tentative quality of *could* questions also makes it less likely that they will be experienced as interrogative.

*Implied questions* are used when an interviewer is interested in receiving more information about a client's thoughts or emotions, but does not want to come across as intrusive. *I wonder* (e.g., "I wonder how you are feeling about the recent job cuts at your workplace.") is an example of an implied question.

Finally, *projective questions* are designed to elicit information about a client's goals, desires, and values. Examples of projective questions include, "Where do you see yourself in a few years from

now?", "What, if anything, would you do differently the next time around?", and "If you could wave a magic wand and make your symptoms disappear, how would things be different for you?" Projective questions in the form of a hypothetical scenario can also provide insight into a client's decision-making processes (e.g., "If you were stuck in a desert for 24 hours, what measures might you take to survive?" (Sommers-Flanagan and Sommers-Flanagan, 2009, p. 217).

### Case Formulation

In the previous sections, the purpose and content of clinical interviewing were discussed, and a detailed description of the types of interviews that are used in clinical practice was provided. This portion of the chapter will focus on *case formulation*—a component of clinical interviewing that is considered a "core therapy skill" (Kendjelic & Eells, 2007). Case formulation is considered to be an integral component of clinical assessment, which is reflected in the proliferation of books (recent examples include Kuyken, Padesky, & Dudley, 2009; Persons, 2008) and scientific articles on the topic in the last 15 years.

### *Case Formulation: Definition and Elements*

Case formulation refers to the construction of an idiographic or individualized explanatory model of the factors that may have caused and precipitated the onset of a client's emotional or behavioral problems and of the factors that may be contributing to their maintenance. It consists of hypotheses about the mechanisms that may underlie a client's presenting problem and predictions about the client's thoughts, emotions, and behaviors in a particular set of situations. Regardless of a clinician's therapeutic orientation, case formulation is considered to be a core aspect of clinical assessment, as it helps both the clinician and client to identify goals for treatment; enables the clinician to devise a treatment plan that is focused and relevant to the client's concerns; and guides clinical decision-making during the course of treatment (Kendjelic & Eells, 2007; Persons, 2006). A well-developed case formulation can also facilitate the early identification of factors that may impede progress in treatment (Eells, 2007; Persons, 2008).

### *Contributions of Different Schools of Psychotherapy to Case Formulation*

Bieling and Kuyken (2003) noted that clinicians generally agree that organizing the client's presenting problems and the factors underlying those problems into a framework or structure is important for clinical assessment and treatment, irrespective of one's psychotherapy orientation. Eells (2007) discusses the contributions of four "schools" of psychotherapy to current approaches to clinical interviewing and case formulation.

Eells (2007) suggests that the *psychoanalytic* approach, as popularized by Freud, brought to the fore the importance of considering the role of personality in psychopathology. Freud's approach to clinical assessment also represented a radical departure from the medical approaches that dominated psychiatry at the time in at least two ways. First, Freud observed that clients often "enacted" their psychological problems during the clinical interview. He suggested that an astute clinician could learn a considerable amount about a client's interpersonal difficulties by paying attention to their verbal and nonverbal behaviors and overall style of interaction during the interview. Eells notes that psychoanalysts rarely mention actual psychiatric diagnoses in their case formulations and focus instead on describing processes or dynamics. The *humanistic* approach (Rogers, 1951) is known for its client-centered focus and emphasizes the importance of collaboration within the clinician–client relationship and of idiographic (as opposed to nomothetic) approaches to formulation. *Cognitive approaches* underscore the contributions of schemata, information processing biases, and negative automatic thoughts to psychopathology. Until recently, a common approach for cognitive therapists was to use general cognitive formulations of psychological disorders to inform treatment planning. For example, a clinician might have used Beck's cognitive theory of depression (see Clark, Beck, & Alford, 1999) to devise a treatment plan for an individual with depression (Eells, 2007). Similarly, Beck and Clark's information processing model of anxiety (1997) describes various cognitive processes that are common across anxiety disorders and is a generic model that can be applied to most forms of anxiety. In recent years, disorder-specific models have proliferated in the clinical and empirical literature. For example, Dugas and colleagues have constructed and tested a cognitive model of generalized anxiety disorder that has led to the development of a psychological treatment that targets each of the components of the model (Dugas & Robichaud, 2007). Eells (2007) noted that there has been an increasing movement in cognitive therapy toward idiographic case formulation. However, it is not known whether there are

any substantial benefits to using individualized cognitive formulations over general formulations; this remains an empirical question (Eells, 2007; Persons & Tomkins, 2007). Central to the *behavioral approach* to case formulation is the *functional analysis*. A functional analysis attempts to identify those factors that are reinforcing a client's problematic behavior. Returning to the example of depression, a clinician working from a more behavioral perspective would concentrate on identifying behaviors that may inadvertently be maintaining the client's difficulties, such as reassurance-seeking and avoidance. Similarly, behavioral formulations of anxiety disorders underscore the roles of escape and avoidance in the maintenance of fear. Eells (2007) discusses three contributions that the behavioral approach has made to current case formulation methods. According to Eells, a relatively unique feature of the behavioral approach to case formulation is that it views maladaptive behaviors as symptoms of psychopathology in and of themselves; therefore, interventions aimed at changing problematic behaviors are, in effect, targeting symptoms of disorder directly. She also proposes that behavioral formulations of psychopathology are grounded in basic experimental research. However, we would contend that these two features are not unique to behavioral approaches; they are also characteristic of cognitive formulations of psychopathology, particularly more recent models that have led to the development of corresponding treatments. Eells proposes that a third important feature of behavioral functional analysis is its explicit emphasis on the identification of external factors (e.g., stressors) that may be contributing to and reinforcing the client's problematic behavior.

### The Role of Case Formulation in Psychological Treatment: Parallels with the Scientific Method

A number of parallels exist between case formulation–driven psychological treatment and the *scientific method* (Persons, 2006). One of the cornerstones of the scientific method is the *hypothesis*. In the process of designing a new experiment, a researcher formulates a tentative, yet informed a priori prediction of what he or she expects to observe in an experiment. To derive this hypothesis, the researcher typically looks to findings documented in the empirical literature, as well as observations that he or she has made in other studies. The first steps in clinical work are not dissimilar from the initial steps that are taken when conducting a scientific study. Before the clini-

cian enters the clinical interview, he or she usually has a minimal amount of information about the client's presenting problem, obtained from a written referral or an existing clinical record. Based on the available information, the clinician devises a preliminary or "working" hypothesis about the nature of the client's difficulties. The working hypothesis might be based on the clinician's past experiences working with clients with similar characteristics or presenting problems, or may be derived from the empirical literature, if the client's stated presenting problem is not one with which the clinician has experience.

During the clinical assessment, the clinician collects data with the aim of testing initial, working hypotheses and developing a more elaborate "theory" of the nature of the client's psychological difficulties that includes possible causes, as well as precipitating and maintaining factors. The clinical interview is the clinician's principal tool for collecting data.

Just as science is "self-correcting," so is the process of case formulation. Over the course of treatment, many of the clinician's observations are likely to be consistent with the original case formulation; however, the clinician may also make observations that run counter to his or her original formulation. Just as scientists are expected to re-examine and revise theories and hypotheses in light of inconsistent data, clinicians are similarly expected to be prepared and open to the possibility that their original formulation of the nature of the client's problems was inaccurate and requires revision. Clinicians ought not to feel compelled to adhere to their initial case conceptualizations for the duration of treatment; flexibility is key. Although the clinical interview does produce a considerable amount of data regarding the client's difficulties, it should be viewed as a strong starting point, as it almost never captures the full range of the client's experience. As such, it is important that clinicians continue to collect data throughout treatment and adjust their case formulations and treatment plans accordingly (Persons, 2006).

### Elements of a Good Case Formulation

Clinicians generally hold the view that a reliable case formulation contributes to the effectiveness of psychological treatment (Persons, Mooney, & Padesky, 1995); however, there is currently little consensus as to what constitutes a "good" case formulation (Flitcroft, James, Freeston, & Wood-Mitchell, 2007). A small number of studies have examined clinicians' beliefs about what amounts to an effective cognitive-behavioral case formulation. In a study by Persons and colleagues (1995), 46 clini-

cians attending a case formulation workshop listened to an audiotaped portion of a clinical interview with two anxious and depressed clients and constructed a cognitive-behavioral case formulation using a well-known protocol by Persons (1989). The case formulation protocol included the following components: identification of the client's actual problem and symptoms (e.g., difficulty functioning at work) and identification of the mechanisms underlying the client's difficulties (e.g., beliefs about the self, world, and others). The findings revealed that there was only a moderate level of agreement in clinicians' identification of clients' actual problems. Agreement between clinicians' conceptualizations of underlying mechanisms was not as high as would be expected, given that all participants were following the same case formulation guidelines.

In a recent extension of the Persons and colleagues study, Flitcroft and colleagues (2007) presented seven clinicians, who identified themselves as cognitive-behavioral therapists, with a clinical case vignette of a man with depressive symptoms. Participants were given a list of 86 features that are characteristics of a cognitive-behavioral case formulation and were asked to indicate which aspects they believed were the most and least essential to a case formulation for depression. Examples of case formulation aspects included, "it identifies precipitating events," "it explains depression at an individual level," and "it identifies typical negative automatic thoughts relating to the self." The findings revealed that there was a high level of agreement that "factual" or descriptive information (e.g., demographic information and medical history) was least essential in the construction of an effective case formulation. On the other hand, there were three distinct views as to what constituted essential features of the formulation: (1) that it have sufficient explanatory power to allow for situation-specific predictions, (2) that it be functional and practical, and (3) that it capture trait-level or dispositional features that may be contributing to the client's difficulties.

## Does Case Formulation Improve Treatment Efficacy?

Although case formulation is not a formal component of the majority of standardized protocols for empirically supported treatments, most clinicians operate on the assumption that case formulation improves treatment outcomes and view it as an important component of clinical assessment and treatment for this reason (Bieling & Kuyken, 2003). Interestingly, only a small number of studies have

been conducted to test the validity and clinical utility of case formulations (Mumma, 2004; Mumma & Mooney, 2007a; 2007b). Bieling and Kuyken (2003) reviewed the findings of three studies that examined the relationship between cognitive case formulation and treatment outcome, and none of the studies provided evidence of a link. Since their review, a few other studies have examined the relationship of case formulation to treatment outcome. These have focused exclusively (to our knowledge) on cognitive or cognitive-behavioral case formulation and treatment. The studies will be described in a considerable amount of detail in the following paragraphs, as they illustrate a range of methodologies that have been employed to test the validity of case formulations.

Using a single-case design methodology, Mumma (2004) assessed the clinical validity of cognitive case formulation for a female client with comorbid mood and anxiety disorders. Mumma conducted an idiographic assessment of the client's cognitive schema using a semi-structured interview that was designed to elicit automatic thoughts and beliefs relevant to her current problems (see Mumma, 2001). The client's verbatim statements were then classified into four categories of depression- and anxiety-related beliefs. The client also completed *standardized* self-report measures of dysfunctional beliefs (e.g., the *Dysfunctional Attitudes Scale*; Weissman, 1979). To validate the hypothesized belief categories derived from the idiographic assessment, Mumma constructed a questionnaire comprised of items derived from the client's verbatim statements in the idiographic assessment, items from the standardized self-report measures, and items from the *Mood and Anxiety Symptoms Questionnaire* (Watson & Clark, 1991). For each item, the client was asked to indicate, using an 11-point scale, the extent to which it was relevant to her experience. The client was asked to complete the questionnaire daily for 90 days.

A factor analysis was performed on the belief items that were derived from the idiographic assessment and revealed a factor structure that supported the four hypothesized categories of cognitions. The four factors derived from the idiographic assessment predicted daily variation in depressive and anxiety symptoms, over and above variation accounted for by the standardized cognitive measures. These findings provide support for the incremental validity of cognitive case formulation.

In a recent investigation, Persons, Roberts, Zalecki, and Brechwald (2006) examined the effectiveness of case-formulation–driven cognitive-behavioral treat-

ment for comorbid mood and anxiety disorders in a sample of 58 clients who received treatment at a private practice clinic specializing in cognitive-behavioral therapy (CBT). Prior to the start of treatment, individualized cognitive-behavioral case formulations were constructed for each client, using a protocol developed by Persons (see Persons & Tomkins, 1997, 2007). Individualized treatment plans were developed based on the idiographic formulations, and treatment strategies were drawn from empirically supported cognitive-behavioral treatment protocols. Clients received approximately 18 sessions of treatment on average. Each client's case formulation and treatment plan were reviewed every three to four sessions and revised as appropriate. Clients completed self-report measures of depressive and anxiety symptoms at each session. Outcomes for case formulation–driven CBT were compared with outcomes from published randomized controlled trials of treatments for individual mood and anxiety disorders (based on the presumption that protocols tested in such trials did not have case formulation as an explicit component). The findings revealed that there were statistically significant reductions in depressive and anxiety symptoms from pre-treatment to post-treatment. Furthermore, the reductions in depressive symptoms were comparable to those documented in published randomized controlled trials of treatments for major depressive disorder. Mean reductions in depression and anxiety were smaller overall for clients who received case formulation treatment relative to means reported in efficacy trials; however, this was likely due to the lower baseline severity of depression and anxiety symptoms in clients in the naturalistic study, as compared with baseline severities reported in the literature.

### Impact of Training on Case Formulation

There appears to be a consensus that providing formalized training in case formulation to beginning therapists is important, the assumption being that such training will enhance clinical decision-making (Kendjelic & Eells, 2007). A small number of studies have examined whether it is possible to train therapists in case formulation and whether such training has an appreciable impact on clinical decision-making. Eells and colleagues (2005) presented novice, experienced, and expert therapists who self-identified as psychodynamic or cognitive-behavioral therapists with 2-minute audiotaped clinical case vignettes describing clients with symptoms that were consistent with generalized anxiety disorder, major depressive disorder, or borderline personality disorder. Using a

"think aloud" procedure, therapists spent 5 minutes developing a case conceptualization and an additional 2 minutes discussing how they would treat the clients. The formulations and treatment plans were recorded and later transcribed and coded. The results showed that expert therapists produced higher-quality formulations relative to the novice and experienced therapists. Specifically, expert formulations were characterized by a higher degree of comprehensiveness, more detailed and nuanced inferences regarding possible mechanisms underlying clients' psychological difficulties, and treatment plans that were more closely linked to formulations. The authors proposed that experts may have employed specific "cognitive skills" when constructing their formulations and treatment plans; however, this was not assessed in the study. The study was unable to identify the skills that may have differentiated the expert therapists from the novice and experienced therapists.

Kendjelic and Eells (2007) recently examined the impact of training on quality of case formulations. Clinicians (75% of whom were trainees) participated in a 2-hour workshop on case formulation that employed a transtheoretical approach developed by the authors, based on a comprehensive review of the literature. The training consisted of education on generic case formulation, which consists of components that were found through the review to be common across psychodynamic, interpersonal, cognitive, and behavioral therapy approaches: identification of symptoms and self-identified problems, identification of predisposing events and conditions, identification of precipitating stressors, and identification of hypothesized mechanisms underlying putative associations between the other three components. Workshop participants also learned strategies for enhancing case formulation. At the end of the session, clinicians were presented with a case vignette and were asked to construct a case formulation.

Trained raters subsequently rated case formulations for quality, complexity, degree of inference, and precision of language. Participants in the training group produced case formulations that were of higher quality, more comprehensive in terms of their representation of the four formulation components, more idiographic, and that contained more information about possible mechanisms than did participants in the no-training condition. Although the findings are preliminary, they suggest that a relatively brief training session on case formulation may improve beginning therapists' skills. The authors proposed that a next step would be to examine

whether the quality of case formulation predicts treatment outcome.

In summary, irrespective of a clinician's theoretical orientation, case formulation is an integral component of assessment that informs efficient and effective treatment planning. Data suggest that training in case formulation improves clinicians' conceptualizations and may contribute to treatment outcome; however, more research is needed to test whether explicit case formulation has a significant impact on treatment efficacy.

## Interviewing Special Populations

In this final section, we will provide an overview of considerations when interviewing special populations. Because of the scope of this chapter, the focus is on considerations as they pertain to couples, individuals from diverse populations, and young individuals.

### Interviewing Couples

The main advantage of the couple interview is that it provides the clinician with the opportunity to observe a couple's interactions, particularly their communication style, in vivo (Duman, Grodin, Cespedes, Fine, Otilingham, & Margolin, 2007). The couple interview can provide richer information than might be obtained if partners were interviewed separately, or if clinicians had access only to clients' self-report of couple difficulties (Duman et al., 2007). The couple interview is an opportunity to observe, "online," verbal and nonverbal exchanges that may be contributing to the couple's problem areas.

A number of considerations present themselves in a multi-individual interview. First, the clinician must create an atmosphere of collaboration, so that partners enter the interview on a "level playing field." Duman et al. (2007) note that the clinician can set the stage for collaboration before the interview begins by positioning chairs so that both partners are sitting at an equal distance from the clinician, at angles that also allow them to face one another. There are two situations in which a couple might be interviewed together: (1) when two partners are seeking treatment and (2) when one partner is brought in to assist with some aspect of the other partner's treatment (e.g., exposure-based therapy). During any couple interview, it is generally important for the clinician to ensure that the couple does not perceive that the clinician is taking the side of one partner versus the other. The clinician can safeguard against this by making certain that both partners are being attended to equally during the interview. The clinician should ensure, for example, that he or she is making eye contact with both partners and that both partners are given an equal opportunity to speak and share their concerns and points of view.

When one partner is invited to participate in an interview to facilitate the other partner's treatment, the clinician's approach to the interview will differ from when a couple is being interviewed as a part of a couple intervention. In cases in which one member of the couple is in treatment, typically, the client's partner is asked to attend only one or two sessions, during which the clinician may ask questions to gain the partner's perspective on the client's difficulties. For example, the partner of a client with obsessive-compulsive disorder might be able to provide additional information about subtle safety behaviors that the client may not be fully aware of, or might be in a position to provide additional information about the extent of the client's functional impairment. The partner is introduced into treatment only if he or she is identified by the client as a trusted and supportive individual who is aware of the client's difficulties and who can provide instrumental support with certain treatment strategies. For example, it is not uncommon to introduce the client's partner into treatment as a "helper" in exposure-based treatment for an anxiety disorder. When the client's partner is introduced into treatment in a facilitative role, the clinician must ensure that the client's partner does not assume a "co-therapist" role, as the client may perceive this as invalidating or even collusive, which could place the therapeutic alliance at risk. Ruptures to the therapeutic alliance can be avoided by having a discussion with the client about the purpose and potential advantages of the partner's involvement in treatment, before the joint interview. The discussion should be transparent, and the clinician should be attentive to and address any misunderstandings regarding the role of the client's partner in the client's treatment. Before the joint interview, the clinician and client should discuss how confidentiality will be handled. Given that the clinician has an obligation to the client to maintain confidentiality, clinicians are advised to consult with clients about topics that are "off-limits" for the joint session; this discussion should be documented in a progress note in the client's clinical record. In many cases, clients will report that they have no concerns about the clinician disclosing information as they have "nothing to hide" from their partner. However, the clinician should not presume that there are no boundaries to confidentiality; because it is the clinician's legal and ethical responsibility to maintain confidentiality, nothing should be taken

for granted. Another way to ensure that the client's goals and needs do not take a backseat in the joint interview is to elicit the active participation of the client during the session, to the extent that the client is comfortable. For example, when a "helper" is brought into treatment to assist the client with exposure practices, part of the meeting is spent providing education to the helper about the client's anxiety disorder. If the psychoeducation is delivered by both the clinician and client, this communicates that the client is "in charge" of his or her own treatment.

### Interviewing Individuals from Diverse Populations

Although a thorough discussion of considerations in multicultural assessment is beyond the scope of this chapter, an overview of some of the main ones will be provided in the following paragraphs. The reader is referred to Aronson Fontes (2008) for a detailed discussion of issues pertaining to multicultural assessment.

During their training, clinicians are made aware of the importance of "considering the role of culture" in clinical assessment and treatment; however, what exactly does it mean to "consider" cultural factors? Before clinicians can begin to consider how cultural factors may be influencing a client's psychological experiences and the communication of those experiences, they must first examine their own understanding of culture. The APA (2003) has adopted a broad stance on diversity that includes the dimensions of race, ethnicity, language, sexual orientation, gender, age, disability, class status, education, religious/spiritual orientation, and "other cultural dimensions." According to this definition, culture and diversity are likely to be a consideration when working with most clients.

Multicultural clinical interviewing proceeds in much the same way as has already been described in this chapter, with an additional focus on the collection of cultural data. As clinicians prepare for the interview, relevant cultural factors should be factored into the preparation. For example, the clinician or interviewer should ensure that any paperwork or forms to be administered to the client are available in the client's language. If materials are not available in the client's language, arrangements should be made for a professional interpreter or translator to attend the assessment. Aronson Fontes (2008) notes that this is an especially important consideration when clinicians are obtaining clients' consent to participate in the interview. Even if a client indi-

cates his or her consent to the clinical assessment by signing the consent form, it should not be taken for granted that the client has understood the purpose and conditions of his or her participation in the interview or that he or she even read the consent form, for that matter. In some cultures, taking the time to read a consent form would constitute a display of distrust toward the clinician (Aronson Fontes, 2008). If an interviewer decides to employ the services of an interpreter, it is important to prepare him or her for the clinical interview, even if the interpreter is experienced and has worked in the same clinical setting as the interviewer in the past. The reader is directed to Aronson Fontes (2008) for a thorough discussion of considerations related to interpreters.

During the actual interview, it is important for clinicians to adopt an unpresumptuous approach when asking questions (Ridley, Li, & Hill, 1998). This is an especially important consideration when a clinician is from the same cultural group as the client, as the clinician might be less inclined to ask the client to elaborate on his or her experiences or might overlook potentially important information. By the same token, the clinician should not bombard the client with questions about his or her cultural group, as this could, paradoxically make the clinician appear unprepared. The onus should not have to be on the client to "educate" the clinician; as such, in preparation for the interview, the clinician should obtain information about the client's cultural group from existing clinical records and from credible Internet sites and books (Aronson Fontes, 2008). Aronson Fontes (2008) also notes that the client's cultural affiliation is not determined by the clinician, but rather by the client. For example, if a client reports that he or she is married to an opposite-sex individual, it should not be assumed that he or she identifies as heterosexual. Such an assumption might preclude the interviewer from asking potentially important questions about the client's sexual practices, resulting in inaccurate information about the client's sexual orientation and sexual identity. As part of the interview, the clinician will also want to obtain information on the degree to which the client has acculturated into the majority culture. See Aronson Fontes (2008) for a list of questions that can be used to assess acculturation, as well as for guidelines on how to ask questions in a non-interrogative style.

During the interview, the clinician is also encouraged to be aware of his or her style of questions. When the client's primary language is different from

interviewer's, the interviewer should minimize use of closed-ended questions that invite responses of "yes" or "no," as there is little way of knowing whether the client truly understood the questions. Whenever possible, the clinician should use terms that are concrete and elicit information about experiences at a behavioral level (e.g., "Have you stopped doing things that you used to enjoy?" versus "Have you been feeling down?"). The clinician is also advised to be mindful of and eliminate behaviors that may be offensive to the client (e.g., speaking in an excessively loud voice with clients whose primary language is not the same as the clinician's).

### Interviewing Young Clients

A number of challenges present themselves when interviewing younger clients. The most notable one is the fact that young clients are typically referred for a clinical interview by their parent, guardian/caretaker, or teacher (Sommers-Flanagan & Sommers-Flanagan, 2009). As such, young clients are usually interviewed with their caretakers present. Sommers-Flanagan and Sommers-Flanagan (2009) note that the manner in which the initial interview with the young client and his or her caretaker is arranged can convey a strong message to both parties; as such, the clinician is advised to be mindful of a number of considerations. First, the clinician should inform the caretaker of the plan for the interview right from the outset. Specifically, the clinician should inform the caretaker that he or she will be interviewed with the young client. The clinician can expect that, if the client is an adolescent or preadolescent, the caretaker may request to speak with the clinician alone first, before beginning the joint interview. If the clinician accepts this request, the young client might gather from this that the clinician and caretaker are colluding, which could have a negative impact on the interview. On the other hand, the caregiver may have a legitimate need to share information with the clinician that is not appropriate to divulge in front of the child. If the child is the "primary client" (Sommers-Flanagan & Sommers-Flanagan, 2009), then the clinician must act in accordance with this and make this clear to the caretaker. For example, the clinician may inform the caretaker at the outset that he or she may share the information that the caretaker provides, as appropriate and at the discretion of the clinician.

Sommers-Flanagan and Sommers-Flanagan (2009) note that clinicians should approach the task of interviewing a younger client as they would the task of interviewing a client from a different cultural background. One of the considerations that should be in the forefront of the clinician's mind while preparing to interview a younger client is the client's stage of development. Clinicians should familiarize themselves with the cognitive, emotional, and behavioral features that characterize different stages of development and modify their interviewing practices accordingly. The reader is referred to Sommers-Flanagan and Sommers-Flanagan (2009) for a detailed comparison of clinical interviewing with young clients versus adult clients.

### Conclusion

As Hunsley and Mash (this volume) note, psychological assessment "is seen as a unique and defining feature of the profession, one that sets us apart from other disciplines involved in providing health-care services." Although clinical assessment has long held a revered place in psychology, there has been a call to re-examine current approaches and procedures in an effort to render them more evidence-based. In their discussion of the limitations of current approaches to clinical assessment, Hunsley and Mash (this volume) argue that, generally, research on psychological assessment has prioritized the construction and validation of empirically derived, psychometrically sound assessment instruments, with insufficient focus on the *incremental validity* and *clinical utility* of these instruments. In this chapter, we have similarly noted that more research is needed on case conceptualization, a core component of clinical interviewing. Specifically, questions still remain as to whether training in case conceptualization increases the quality of formulations, whether explicit case conceptualization enhances treatment efficacy, and whether idiographic case conceptualizations are superior to "generic" variants. Like Hunsley and Mash (this volume), we are also of the view that research on clinical assessment should focus on addressing questions about the reliability, incremental validity, and clinical utility of current assessment approaches, if the field is to move forward.

# Diagnoses, Dimensions, and DSM-5

Thomas A. Widiger *and* Maryanne Edmundson

### Abstract

The *Diagnostic and Statistical Manual of Mental Disorders*, *Third Edition* (DSM-III) is often said to have provided a significant paradigm shift in how psychopathology is diagnosed. The authors of DSM-5 have the empirical support and the opportunity to lead the field of psychiatry to a comparably bold new future in diagnosis and classification. The purpose of this chapter is to address the validity of the categorical and dimensional models for the classification and diagnosis of psychopathology. Considered in particular will be research concerning substance use disorders, mood disorders, and personality disorders. Limitations and concerns with respect to a dimensional classification of psychopathology are also considered. The chapter concludes with a recommendation for a conversion to a more quantitative, dimensional classification of psychopathology.

**Key Words:** Categorical, classification, diagnosis, dimensional, DSM-5, validity

The *Diagnostic and Statistical Manual of Mental Disorders* (DSM) is the classification of psychopathology developed under the authority of the American Psychiatric Association (APA), the current version of which is DSM-IV-TR (APA, 2000). The primary purpose of an official diagnostic nomenclature is to provide a common language of communication (Kendell, 1975; Sartorius et al., 1993), the absence of which essentially incapacitates communication among clinicians and researchers. Official diagnostic nomenclatures, however, can be exceedingly powerful, impacting many important social, scientific, forensic, clinical, and other professional decisions (Schwartz & Wiggins, 2002). Persons think in terms of their language, and the predominant language of psychopathology is DSM-IV-TR. As such, DSM-IV-TR has a substantial impact on how clinicians, scientists, and the general public conceptualize aberrant, problematic, and maladaptive behavior.

"DSM-IV is a categorical classification that divides mental disorders into types based on criterion sets with defining features" (APA, 2000, p. xxxi).

The categorical model of classification is consistent with a medical tradition in which it is believed (and often confirmed in other areas of medicine) that disorders have specific etiologies, pathologies, and treatments (Guze, 1978; Guze & Helzer, 1987; Zachar & Kendler, 2007). Clinicians, following this lead, diagnose and conceptualize the conditions presented in DSM-IV-TR as disorders that are qualitatively distinct from normal functioning and from one another. Clinicians devote initial time with a new patient to identify, through differential diagnosis, which specific disorder best explains a patient's presenting complaints. Authors of the diagnostic manual devote a considerable amount of time writing, revising, and researching diagnostic criteria to improve differential diagnosis, and scientists may devote their careers to attempting to identify the specific etiology, pathology, or treatment for a respective diagnostic category.

The principal model for the validation of distinct diagnostic categories was provided by Robins and Guze (1970), who articulated five fundamental

phases: clinical description, laboratory study, delimitation from other disorders, follow-up, and family studies. However, the question of whether mental disorders are in fact discrete clinical conditions or arbitrary distinctions along continuous dimensions of functioning has been a longstanding issue (Kendell, 1975) and its significance is escalating with the growing recognition of the limitations of the categorical model (Widiger & Clark, 2000; Widiger & Samuel, 2005). As expressed by the Vice Chair of DSM-5, "the failure of DSM-III criteria to specifically define individuals with only one disorder served as an alert that the strict neo-Kraepelinian categorical approach to mental disorder diagnoses advocated by Robins and Guze (1970), Spitzer, Endicott, & Robins (1978), and others could have some serious problems" (Regier, 2008, p. xxi).

In 1999, a DSM-5 Research Planning Conference was held under joint sponsorship of the APA and the National Institute of Mental Health (NIMH), the purpose of which was to set research priorities that would optimally inform future classifications. An impetus for this effort was the frustration with the existing nomenclature (Kupfer, First, & Regier, 2002). At this conference, DSM-5 Research Planning Work Groups were formed to develop white papers that would set an effective research agenda for the forthcoming revision of the diagnostic manual. The Nomenclature Work Group, charged with addressing fundamental assumptions of the diagnostic system, concluded that it will be "important that consideration be given to advantages and disadvantages of basing part or all of DSM-5 on dimensions rather than categories" (Rounsaville et al., 2002, p. 12).

The white papers developed by the DSM-5 Research Planning Work Groups were followed by a series of international conferences whose purpose was to further enrich the empirical data base in preparation for the eventual development of DSM-5 (a description of this conference series can be found at http://www.dsm5.org). The first conference was devoted to shifting personality disorders to a dimensional model of classification (Widiger, Simonsen, Krueger, Livesley, & Verheul, 2005). The final conference was devoted to dimensional approaches across the diagnostic manual, including substance use disorders, major depressive disorder, psychoses, anxiety disorders, and developmental psychopathology, as well as the personality disorders (Helzer, Kraemer, et al., 2008).

The purpose of this chapter is to address the validity of the categorical and dimensional models for the classification and diagnosis of psychopathology.

Considered in particular will be research concerning substance use disorders, mood disorders, and personality disorders. Limitations and concerns with respect to a dimensional classification of psychopathology are also considered. The chapter concludes with a recommendation for a conversion to a more quantitative, dimensional classification of psychopathology.

## Dimensional Models for DSM-5

One of the more problematic findings for the validity of the DSM-IV-TR categorical model of classification has been the excessive comorbidity among diagnoses (Krueger & Markon, 2006; Maser & Patterson, 2002; Widiger & Clark, 2000). The term "comorbidity" refers to the co-occurrence of distinct disorders, apparently interacting with one another, and each presumably with its own etiology, pathology, and treatment implications (Feinstein, 1970). However, in the case of psychopathology, comorbidity may be saying more about the invalidity of existing diagnostic distinctions than the presence of multiple conditions (Krueger, 2002).

DSM-IV-TR provides diagnostic criterion sets to help guide clinicians toward a purportedly correct diagnosis and an additional supplementary section devoted to differential diagnosis that indicates "how to differentiate [the] disorder from other disorders that have similar presenting characteristics" (APA, 2000, p. 10). The intention of the diagnostic manual is to help the clinician determine which particular mental disorder is present, the selection of which would presumably indicate the presence of a specific pathology that will explain the occurrence of the symptoms and suggest a specific treatment that will ameliorate the patient's suffering (Frances, First, & Pincus, 1995; Kendell, 1975). Considerable effort is spent by the authors of each edition of the diagnostic manual to further buttress each disorder's criterion set, trying to shore up discriminant validity and distinctiveness, following the rubric of Robins and Guze (1970) that the validity of a diagnosis rests in large part on its "delimitation from other disorders" (p. 108). "These criteria should … permit exclusion of borderline cases and doubtful cases (an undiagnosed group) so that the index group may be as homogeneous as possible" (Robins & Guze, 1970, p. 108). Indeed, as acknowledged more recently by Kendell and Jablensky (2003), "if no detectable discontinuities in symptoms are found in large tracts of the territory of psychiatric disorder, it is likely that, sooner or later, our existing typology will be abandoned and replaced by a dimensional classification" (p. 8).

In an effort to force differential diagnosis, a majority of diagnoses in DSM-III (APA, 1980) contained exclusionary criteria specifying that a respective disorder could not be diagnosed if it could in fact be due to another disorder. These exclusions by fiat did not prove to be at all effective (Boyd et al., 1984) and many were deleted in DSM-III-R (APA, 1987). As expressed at the time by Maser and Cloninger (1990), "It is clear that the classic Kraepelinian model in which all psychopathology is comprised of discrete and mutually exclusive diseases must be modified or rejected" (p. 12).

Many DSM-IV-TR diagnostic criterion sets, however, continue to contain exclusionary criteria that attempt to force clinicians to make largely arbitrary choices among competing diagnoses (APA, 2000), and it is also evident that there is a highly problematic rate of diagnostic co-occurrence (Kessler, Chiu, Dember, & Walters, 2005). If one considers the entire diagnostic manual (which has not yet been done by any epidemiologic study), it would likely be exceedingly rare for any single patient to meet the criteria for just one disorder, and the comorbidity rises even further if one considers co-occurrence of lifetime disorders. Brown, Campbell, Lehman, Grisham, and Mancill (2001) reported that 95% of individuals in a clinical setting who meet criteria for lifetime major depression or dysthymia also meet criteria for a current or past anxiety disorder.

"The greatest challenge that the extensive comorbidity data pose to the current nosological system concerns the validity of the diagnostic categories themselves—do these disorders constitute distinct clinical entities?" (Mineka, Watson, & Clark, 1998, p. 380). Diagnostic comorbidity has become so prevalent that some researchers have argued for an abandonment of the term "comorbidity" in favor of a term (e.g., "co-occurrence") that is more simply descriptive and does not imply the presence of distinct clinical entities (Lilienfeld, Waldman, & Israel, 1994). There are instances in which the presence of multiple diagnoses do suggest the presence of distinct yet comorbid psychopathologies, but in most instances the presence of co-occurring diagnoses does appear to suggest the presence of a common, shared pathology (Clark, 2005; Krueger & Markon, 2006; Watson, 2005; Widiger & Clark, 2000). "Comorbidity may be trying to show us that many current treatments are not so much treatments for transient 'state' mental disorders of affect and anxiety as they are treatments for core processes, such as negative affectivity, that span normal and abnormal variation as well as undergird multiple mental disorders" (Krueger, 2002, p. 44).

New diagnostic categories are added to the nomenclature in large part to decrease clinicians' reliance on the nonspecific, wastebasket label of "not otherwise specified" (NOS). NOS is among the most frequent disorders within clinical populations (Clark, Watson, & Reynolds, 1995; Verheul & Widiger, 2004). Diagnostic criteria are developed and modified in order to construct a disorder that is as homogeneous as possible, thereby facilitating the likelihood of identifying a specific etiology, pathology, and treatment (Robins & Guze, 1970). However, the typical result of this effort is to leave many cases unaccounted for. In addition, despite the best effort to construct homogeneous and distinct syndromes, DSM-IV-TR is still replete with heterogeneous conditions with overlapping boundaries (Smith & Combs, in press). The function of most of the new disorders that are added to the diagnostic manual doesn't appear to involve the identification of uniquely new forms of psychopathology. Their purpose is generally instead to fill problematic gaps. Notable examples of DSM-IV included bipolar II (filling a gap between DSM-III-R bipolar and cyclothymic mood disorders), mixed anxiety-depressive disorder (a gap between anxiety and mood disorders), depressive personality disorder (personality and mood disorders), and postpsychotic depressive disorder of schizophrenia (schizophrenia and major depression) (Frances et al., 1995).

When new diagnoses are added to fill the gaps, they have the ironic effect of creating additional boundary problems, thereby making the problem of differential diagnosis even worse (Phillips, Price, Greenburg, & Rasmussen, 2003; Pincus, McQueen, & Elinson, 2003). One must ask whether it is really meaningful or useful to argue or decide whether mixed anxiety-depressive disorder is a mood or an anxiety disorder, whether schizoaffective disorder is a mood disorder or a form of schizophrenia (Craddock & Owen, 2005), whether postpsychotic depressive disorder of schizophrenia is a form of depression or schizophrenia, whether early-onset dysthymia is a mood or a personality disorder (Widiger, 2003), whether acute stress disorder is an anxiety or a dissociative disorder (Cardena, Butler, & Spiegel, 2003), whether hypochondriasis is an anxiety disorder or a somatoform disorder, whether body dysmorphic disorder is an anxiety, eating, or somatoform disorder, and whether generalized social phobia is an anxiety or a personality disorder (Widiger, 2001a). Yet these arbitrary and procrustean decisions must be made by the authors of

a categorical diagnostic manual, and a considerable amount of effort and research is conducted to guide their decision, followed by further discussion and research to refute and debate whatever particular categorical decision was made.

## Internalization and Externalization

As stated in DSM-IV-TR, "a categorical approach to classification works best when all members of a diagnostic class [e.g., mood disorder] are homogeneous, when there are clear boundaries between classes [e.g., mood and anxiety disorders], and when the different classes are mutually exclusive" (APA, 2000, p. xxxi). Nevertheless, it is quite evident from the comorbidity research that much diagnostic co-occurrence cuts across the major classes of anxiety, mood, substance use, psychotic, and personality disorders (Mineka et al., 1998). Achenbach and colleagues, quite a number of years ago, identified and subsequently validated two fundamental dimensions of psychopathology, internalization and externalization, that cut across and largely explained the co-occurrence among existing diagnostic categories of childhood (Achenbach, 1966; Achenbach & Edelbrock, 1978, 1984). Internalizing disorders included shy, anxious, depressive, inhibited, over-controlled behaviors, whereas externalizing involved aggressive, impulsive, acting-out, and conduct disordered behaviors. Achenbach and colleagues suggested that these two broad dimensions, along with empirically identified facets within each, would likely have more support as endophenotypic latent constructs with specific treatment implications than the existing diagnostic categories. These dimensions of Achenbach continue to have a strong impact on the study and understanding of childhood psychopathology (e.g., Lahey et al., 2004).

The internalization-externalization distinction of Achenbach and colleagues has been more recently applied to adult disorders of psychopathology, perhaps now to a much more receptive audience. Krueger and colleagues in particular have replicated the existence of these two broad domains using a variety of methods and sampling from a wide variety of populations. As suggested by Achenbach, internalizing is distinguished by prominent problems with negative emotion, and it influences liability to disorders such as major depression, generalized anxiety disorder, phobias, panic disorder, obsessive-compulsive disorder, and post-traumatic stress disorder. Externalizing also involves negative affectivity, along with disinhibition or impulsivity, and influences liability to disorders such as substance abuse

and dependence, antisocial personality disorder, and conduct disorder. As Achenbach had predicted, these superordinate dimensions have been successful in accounting for relationships among common forms of psychopathology (Krueger & Markon, 2006) and in helping to explain their etiology (Krueger, 2002). Kendler, Prescott, Myers, and Neale (2003), for instance, demonstrated that the comorbidity across major depression, generalized anxiety disorder, phobia, alcohol dependence, drug abuse and dependence, antisocial personality disorder, and conduct disorder does appear to concern a shared variance with individual differences in genetic structure. The "results suggest strongly that genetic factors are largely responsible for the pattern of comorbidity that results in the two frequently co-occurring clusters of internalizing and externalizing disorders" (Kendler et al., 2003, p. 253).

There is, of course, much that stills need to be done with respect to these two broad constructs. For one, it isn't yet really clear how the APA diagnostic manual could in fact be re-organized with respect to internalization and externalization. The numerical coding system of the DSM-IV-TR may not even be able to provide any official recognition of a construct that cuts across different classes of disorders (Frances et al., 1995). In addition, there are many mood, anxiety, and personality disorder constructs that have typically been left out of the analyses, and many disorders outside of these broad classes of psychopathology that have been largely neglected (e.g., psychotic disorders, impulse dyscontrol disorders, paraphilias, and sex dysfunctions).

Perhaps most importantly, the explanatory power of the internalization and externalization constructs is not really clear. The constructs of internalization and externalization sound quite distinct, but they are typically highly correlated (e.g., Krueger et al., 1998; Lahey et al., 2008) and may not be that well distinguished conceptually. Krueger and Tackett (2003) suggest that the labels "make psychological sense… the internalizing disorders are associated with negative emotionality, whereas the externalizing disorders are associated with negative emotionality and a lack of constraint" (p. 121). However, it is perhaps problematic for their conceptual understanding and distinction to have both dimensions be heavily saturated with neuroticism or negative affectivity. The dimensions do not in fact appear to be well distinguished with respect to fundamental temperaments, which would presumably provide an important foundation and disposition toward the development of the respective DSM-IV-TR disorders

(Clark & Watson, 2008). Lahey et al. in fact noted that major depressive disorder and generalized anxiety disorder loaded on "externalizing" as well as "internalizing." They suggest that their "findings are consistent with the idea that dimensions of DSM-IV symptoms are hierarchically organized within such broad 'internalizing' and 'externalizing' dimensions (Krueger, 1999), but the nature of those broad dimensions will need to be reconsidered" (p. 203).

It might be useful if scales were developed to assess internalization and externalization rather than simply reproducing them in a somewhat different manner with each new study that organizes DSM-IV-TR disorders and/or symptoms in terms of the two respective dimensions. Researchers could then conduct studies that are more specifically concerned with their construct validity (Smith & Combs, in press). Achenbach and colleagues did develop instruments and scales for their assessment in children and adolescents (Achenbach, 1991; Achenbach & Rescorla, 2001) and perhaps their lead should again be followed in the further development and validation of these same constructs within adulthood.

Just as a factor analysis of heterogeneous scales or items will lack clear meaning, so will a factor analysis of a set of heterogeneous disorders. It would be useful to further differentiate each heterogeneous disorder (e.g., depression, borderline personality disorder) into its homogeneous components, and then factor analyze those components. This would more likely result in meaningful higher-order dimensions (Smith & Combs, in press). The purpose of an empirically derived hierarchical model of classification is not simply to provide a means with which to reproduce fundamentally flawed diagnostic categories that represent constellations of heterogeneous and overlapping symptoms, but to instead replace these flawed diagnoses with more specific and clearly defined constructs that are then more likely to have specific etiologies, pathologies, and treatment implications (Clark, 2007). Some progress in this area has begun (e.g., the distinction between distress and fear within the internalization domain; Watson, 2005). Indeed, homogeneous dimensions for many DSM-IV-TR disorders have been identified (Smith & Combs, in press).

## Intellectual Disability

Many persons write as if a shift to a dimensional classification represents a new, fundamental change to the diagnostic manual (e.g., Regier, 2008; Rounsaville et al., 2002), and for much of the manual, diagnosing

mental disorders on a continuum that shades imperceptibly into normal psychological functioning would certainly represent a fundamental change in how mental disorders are conceptualized and classified (Guze, 1978; Guze & Helzer, 1987; Robins & Guze, 1970). Nevertheless, there is a clear precedent for a dimensional classification of psychopathology already included within DSM-IV-TR: the diagnosis of mental retardation (APA, 2000).

Mental retardation in DSM-IV-TR is diagnosed along a continuum of intellectual and social functioning; more specifically, "significantly subaverage intellectual functioning: an IQ [intelligence quotient] of approximately 70 or below" (APA, 2000, p. 49), along with related deficits or impairments in adaptive functioning. An IQ of 70 does not carve nature at a discrete joint or identify the presence of a qualitatively distinct condition, disease, or disorder. On the contrary, it is a quantitatively arbitrary cutoff point along a continuum of functioning. An IQ of 70 is simply two standard deviations below the mean of an appropriate assessment instrument (American Association on Mental Retardation [AAMR], 2002).

Intelligence involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly, and learn from experience (AAMR, 2002). It is distributed as a hierarchical, multifactorial continuous variable, as most persons' levels of intelligence, including most of those with mental retardation, is the result of a complex interaction of multiple genetic, fetal, and infant development, and environmental influences (Deary, Spinath, & Bates, 2006; Gray & Thompson, 2004). There are no discrete breaks in its distribution that would provide an absolute distinction between normal and abnormal intelligence. The point of demarcation for the diagnosis of an intellectual disability (the more current term for the disorder; Schalock et al., 2007) is an arbitrary, quantitative distinction along the normally distributed levels of hierarchically and multifactorially defined intelligence (i.e., two standard deviations below the normative mean). This point of demarcation is arbitrary in the sense that it does not correspond with a distinct, natural joint, but neither was it randomly or mindlessly chosen. It is a defensible selection that was informed by the impairments in functioning commonly associated with an IQ of 70 or below (AAMR, 2002).

In addition, the disorder of mental retardation is not diagnosed simply by the presence of an IQ of 70 or below. It must be accompanied by a documented impairment to functioning. "Mental retardation is a

disability characterized by significant limitation in both intellectual functioning and in adaptive behavior as expressed in conceptual, social, and practical adaptive skills" (AAMR, 2002, p. 23). The purpose of the diagnosis is not to suggest that a specific pathology is present, but to identify persons who, on the basis of their intellectual disability, would be eligible for services and benefits to help them overcome or compensate for their relatively lower level of intelligence.

IQ scores, of course, must always be considered in light of the standard error of measurement, which for most IQ tests is approximately 5, and so an IQ as high as 75 may also be diagnosed. In addition, the diagnosis of mental retardation must also be considered relative to the adaptive behaviors the persons must learn to function in their everyday lives, not with respect to a notion of a maximal or absolute performance (AAMR, 2002). Those with IQ scores lower than 70 who can function effectively would not be diagnosed; hence, the diagnosis is understood in the context of the social, practical requirements of everyday functioning that must be met by the person (Luckasson & Reeve, 2001).

It is certainly the case that many instances of intellectual disability are due to specific etiologies, such as tuberous sclerosis, microcephaly, von Recklinghausen disease, trisomy 21, mosaicism, Prader-Willi syndrome, and many, many more (Kendell & Jablensky, 2003). Nevertheless, the disorders that result from these specific etiologies are generally understood as medical conditions, an associated feature of which is an intellectual disability that would be diagnosed concurrently and independently as mental retardation. The intellectual disability that is diagnosed as a mental disorder within DSM-IV-TR is itself a multifactorially determined and heterogeneous dimensional construct falling along the broad continuum of intellectual functioning. "The causes of intellectual disabilities are typically complex interactions of biological, behavioral/psychological, and sociocultural factors" (Naglieri, Salter, & Rojahn, 2008, p. 409). An important postnatal cause for intellectual disability is "simply" psychosocial deprivation, resulting from poverty, chaotic living environment, and/or child abuse or neglect. As expressed in DSM-IV-TR, "in approximately 30%–40% of individuals seen in clinical settings, no clear etiology for the mental retardation can be determined despite extensive evaluation efforts" (APA, 2000, p. 45). In sum, in the classification of intellectual disability (mental retardation), one diagnoses a multifactorial disorder

on the basis of a normative cutoff point and level of impairment without any implication of there being a qualitative distinction.

## Alcohol Abuse and Dependence

One of the sections of the DSM-IV-TR for which a categorical model of classification and conceptualization has had a long and firmly entrenched tradition is the substance use disorders. Alcoholism in particular has a long tradition of being conceptualized as a qualitatively distinct disease (Garbutt, 2008; Goodwin & Guze, 1996; Jellinek, 1960). A significant change to its diagnosis and conceptualization occurred with DSM-III-R (APA, 1987) when it shifted from being understood as a purely physiological dependence to a broader and less specific behavioral dependence (Carroll, Rounsaville, & Bryant,1994; Edwards & Gross, 1976). "Dependence is seen as a complex process that reflects the central importance of substances in an individual's life, along with a feeling of compulsion to continue taking the substance and subsequent problems controlling use" (Schuckit et al., 1999, p. 41). To many, the diagnosis does still refer to a disease, but one that is developed through a social learning history (Kandel, 1998). It is perhaps time for a further fundamental shift in how this disorder is diagnosed and conceptualized.

One of the difficulties plaguing the diagnoses of alcohol dependence and abuse is the lack of a meaningful distinction between these two diagnostic categories. Abuse is generally considered to be simply a residual category and/or a less severe form of dependence (Saunders, 2006). Some of the diagnostic criteria for abuse are contained with the criterion set for dependence (e.g., interference with social, occupational, or recreational activities), which is always a problem for disorders that would be considered to be qualitatively distinct conditions. A related problem for the alcohol use disorder diagnoses (as well as for other substance use disorders) is the failure of either diagnostic category to adequately capture or cover a number of additional dyscontrolled and harmful patterns of alcohol use (Saunders, 2006). These failings could all reflect limitations that will be inherent to any effort to impose categorical diagnostic distinctions onto what is more validly understood to be a continuum of dyscontrolled and impairing alcohol usage (Widiger & Smith, 1994).

The diagnostic criteria for alcohol dependence were written largely in an effort to describe a prototypic case of this disorder, a practice that is largely followed for all but a few of the disorders in DSM-IV-TR

(Frances et al., 1995). However, prototypic cases are typically understood to be the most severe cases and/or those cases that involve all possible features or symptoms of the disorder (First & Westen, 2007). The diagnosis of an individual involves either counting up the number of features of these prototypic (most severe) cases that are present in the individual (Spitzer, Williams, & Skodol, 1980) or more subjectively matching the actual case to these prototypes (First & Westen, 2007).

The construction of diagnostic criterion sets in terms of prototypic cases does work to an extent, but it will also fail to adequately describe many of the actual cases, the subthreshold cases, and perhaps even the typical cases, depending upon the distribution of features and symptomatology within the general population. This approach is comparable to confining the description and diagnosis of mental retardation to the most severe variant of intellectual disability, and then attempting to apply this description to all of the less-severe variants; a method of diagnosis that would obviously be sorely limited. The limitations of this approach are now becoming more closely appreciated in the diagnosis of dyscontrolled substance use and, more specifically, alcohol use disorders, in which the existing criterion sets are failing to adequately describe dyscontrolled and impairing alcohol usage in adolescents (Crowley, 2006) and other "diagnostic orphans" (Saunders, 2006).

The limitation is perhaps most clearly demonstrated in studies using item response theory (IRT) methodology. Item response theory allows the researcher to investigate the fidelity with which items are measuring a latent trait along the length of its continuum, contrasting, for instance, the amount of information that different diagnostic criteria provide at different levels of a latent trait underlying the diagnostic construct (Muthen, 2006). A number of IRT analyses have now been conducted, and the findings are quite consistent (Reise & Waller, 2009. The existing diagnostic criterion sets (and/or symptoms currently assessed in existing instruments) cluster around the high end of the disorder, as opposed to being spread out across the entire range of the continuum (e.g., Kahler & Strong, 2006; Krueger et al., 2004; Langenbucher et al., 2004; Muthen, 2006; Proudfoot, Baillie, & Teesson, 2006; Saha, Chou, & Grant, 2006). This consistent pattern of results is in stark contrast to what is traditionally found in cognitive ability testing, where IRT analyses have been largely developed and previously applied (Reise & Waller, 2009. It is also worth noting that the diagnostic criteria for abuse are not consistently providing information for a lower level of alcoholism severity (when compared to diagnostic criteria for dependence), and are at times providing more information than some dependency criteria at the higher levels of severity for the disorder (Kahler & Strong, 2006; Saha et al., 2006).

It is evident from the IRT analyses that the existing diagnostic criterion sets are sorely inadequate in characterizing the lower and even middle range of substance use dysfunction, consistent with the DSM-IV-TR description being confined to a prototypic case (of the presumably qualitatively distinct disorder). If alcohol usage was conceptualized along a continuum, the job of the authors of the diagnostic manual would be instead to construct a description and measurement of the disorder that adequately represents each of the levels or degrees to which the disorder appears along this continuum. Instead, the existing criterion sets are confined to only the most severe cases and are not describing well a large proportion of persons with clinically significant alcohol use dysfunction, and, as a result, clinicians must continue to rely on the nondescriptive, wastebasket diagnosis of NOS (Saunders, 2006).

Reise and Waller (2009) suggest that the IRT anomaly for substance use and other areas of psychopathology is a reflection of a "quasi-trait" status for many diagnostic constructs, by which they mean that the trait is unipolar (i.e., relevant only in one direction). Variation at the low end is relatively less informative because persons at the low end simply lack any meaningful variation with respect to the construct (e.g., absence of alcohol use symptomatology). This interpretation, however, might in fact be understood as being inconsistent with a dimensional understanding of the latent construct (i.e., the continuum only reflects a severity of dysfunction among persons with the disorder, rather than a broader continuum within the general population). One taxometric study has supported a latent categorical taxon for alcoholism (Walters, 2008). However, the bulk of the existing research does appear to be most consistent with the hypothesis that alcohol use disorders are best understood as a continuous distribution shading imperceptibly into normal, relatively nonharmful alcohol usage (Hasin, Liu, Alderson, & Grant, 2006; Muthen, 2006).

Further research, however, should perhaps explore the precise nature of the latent trait underlying the substance use continuum, particularly the trait that is being modeled in existing IRT and related research; more specifically, the extent to which the

continuum may reflect simply a severity of impairment rather than a degree of dyscontrolled usage (Widiger & Smith, 1994). All mental disorders can be ranked along a common level of impairment (e.g., Axis IV of DSM-IV-TR; APA, 2000), and each disorder within each class of disorder (e.g., substance use) can be similarly ranked along this common continuum. For example, embedded within indicators of dyscontrol (e.g., drinking more than originally intended) are indicators of impairment secondary to this dyscontrol (e.g., problems with relationships, employment, arrests, and costs to physical health). These indicators of impairment will be seen in other disorders (i.e., level of impairment is a dimension common across all disorders). It is possible that the latent trait being identified and analyzed for different mental disorders in IRT analyses are not actually specific to each particular disorder (reflecting a continuum of that respective disorder), but perhaps measure instead the fact that all disorders vary in level of severity (even those that could in fact be qualitatively distinct medical conditions).

## Depression

The mood disorders is a section of the APA diagnostic manual for which the presence of qualitatively distinct conditions is difficult to defend, particularly for the primary diagnoses of dysthymia and major depressive disorder. Discussed here will be early-onset dysthymia, the continuum of depression, and subthreshold major depression, along with more general points concerning the boundary between Axis I and Axis II disorders.

### Early-onset Dysthymia

There is no meaningful distinction between early-onset dysthymia, an officially recognized mood disorder diagnosis, and depressive personality disorder, a proposed diagnosis within an appendix to DSM-IV-TR (APA, 2000). In fact, much of the empirical and conceptual basis for adding dysthymia to the DSM-III (APA, 1980) came from research and clinical literature concerning depressive personality (Keller, 1989). As acknowledged by the principal architects of DSM-III, dysthymia is "roughly equivalent to the concept of depressive personality" (Spitzer, Williams, & Skodol, 1980, p. 159). Depressive personality disorder was included within the mood disorders section of DSM-III despite the recommendations to recognize its existence as a personality disorder (Klerman, Endicott, Spitzer, & Hirschfeld, 1979) because it resembled the symptomatology of other

mood disorders (i.e., depressed mood) more than it resembled the symptoms of other personality disorders (e.g., schizoid). However, whereas mood disorders are defined largely by similarity in content (i.e., mood being the predominant feature; APA, 2000), the personality disorders are defined largely by form (i.e., early onset, pervasive, and chronic), often with quite different content (e.g., schizoid also shares little resemblance to histrionic personality disorder).

After DSM-III was published, it became evident that many of the persons who were consistently and characteristically pessimistic, gloomy, cheerless, glum, and sullen (i.e., dysthymic) had been that way since childhood and that, in many cases, no apparent or distinct age of onset could be established. DSM-III-R therefore added an early-onset subtype (APA, 1987) and acknowledged that "this disorder usually begins in childhood, adolescence, or early adult life, and for this reason has often been referred to as a Depressive Personality" (APA, 1987, p. 231).

Personality disorder researchers made a further proposal for the inclusion of a depressive personality disorder (DPD) for DSM-IV. They were told that, in order for it to be included, it needed to be distinguished from the already established diagnosis of early-onset dysthymia, a task that might be considered rather difficult, if not unfair, given that the latter construct was based in large part on the former construct. Nevertheless, the DSM-IV Personality Disorders Work Group developed a proposed diagnostic criterion set that placed relatively more emphasis on cognitive features not currently included within the criterion set for dysthymia, as well as excluding somatic features (Task Force, 1991). This criterion set was provided to the DSM-IV Mood Disorders Work Group to include within their DSM-IV field trial to determine empirically whether it was indeed possible to demarcate any area of functioning not yet covered by early-onset dysthymia or at least identify persons not yet meeting diagnostic criteria for early-onset dysthymia.

The proposed criterion set was in fact successful in reaching this goal (Phillips et al., 1998), which perhaps should not be surprising, as no criterion set for a categorical diagnosis appears to be entirely successful in covering all cases. However, the Mood Disorders Work Group was equally impressed with the potential utility of the DPD diagnostic criteria for further describing and expanding the coverage of dysthymia (Keller et al., 1995) and therefore incorporated much of the proposed criteria for DPD into their proposed revisions for dysthymia

(Task Force, 1993). The DSM-IV Task Force recognized that it might be problematic to now require the personality disorder researchers to further redefine DPD to distinguish it from this further revision of dysthymia. The DSM-IV Task Force decided instead to include both criterion sets in the appendix to DSM-IV (along with the original criterion set for dysthymia within the mood disorders section), with the acknowledgment that there may not be any meaningful distinction between them (APA, 2000 Frances et al., 1995).

The issues and concerns that plague any distinction between early-onset dysthymia and depressive personality disorder are also readily apparent for many other boundaries between the personality disorders and Axis I disorders (Krueger, 2005), particularly the distinction between generalized social phobia and avoidant personality disorder (Schneider, Blanco, Anita, & Liebowitz, 2002; Widiger, 2003). In fact, many, if not most, of the personality disorders can be understood, in part, as early-onset variants of Axis I disorders (Krueger, 2005; Widiger, 2003). In addition to the avoidant and depressive personality disorders, borderline personality disorder could be reconceptualized as an affective dysregulation disorder (Linehan, 2000); schizoid as an early-onset and chronic variant of the negative (anhedonic) symptoms of schizophrenic pathology (Miller, Useda, Trull, Burrs, & Minks-Brown, 2001; Parnas, Licht, & Bovet, 2005); paranoid personality disorder by an early onset, chronic, and milder variant of a delusional disorder; obsessive-compulsive personality disorder by a generalized and chronic variant of obsessive-compulsive anxiety disorder (although there is in fact only weak evidence to support a close relationship between the obsessive-compulsive anxiety and personality disorders; Costa, Samuels, Bagby, Daffin, & Norton, 2005); and antisocial personality disorder by an adult variant of conduct (disruptive behavior) disorder. The World Health Organization's (WHO) International Classification of Diseases (ICD-10; WHO, 1992), the parent classification to the APA diagnostic manual, already includes schizotypal personality disorder within the section of the manual for disorders of schizophrenia, not recognizing the existence of DSM-IV-TR schizotypal personality disorder. There is a good possibility that the authors of DSM-5 will follow this lead (First et al., 2002; Siever & Davis, 1991).

Support for conceptualizing schizotypal personality disorder as a form of schizophrenia includes that it is genetically related to schizophrenia, most of its neurobiological risk factors and psychophysiological correlates are shared with schizophrenia (e.g., eye tracking, orienting, startle blink, and neurodevelopmental abnormalities), and the treatments that are effective in ameliorating schizotypal symptoms overlap with treatments used for persons with Axis I schizophrenia (Lenzenweger, 2006). Nevertheless, inconsistent with the ICD-10 classification of schizotypal personality disorder as a form of schizophrenia is that it is far more comorbid with other personality disorders than it is with psychotic disorders, persons with schizotypal personality disorder rarely go on to develop schizophrenia, and schizotypal symptomatology is seen in quite a number of persons who appear to lack a genetic association with schizophrenia and would not be at all well described as being schizophrenic (Raine, 2006).

An additional concern with reformulating personality disorders as early-onset and chronic variants of Axis I disorders, including dysthymia, beyond the fundamental consideration that the diagnostic manual would no longer recognize the existence of maladaptive personality functioning, is that it might create more problems than it solves. It does appear to be true that persons have constellations of maladaptive personality traits that are not well described by just one or even multiple personality disorder diagnoses (Widiger & Trull, 2007). These constellations of maladaptive personality traits would be even less well described by multiple Axis I diagnoses across broad classes of anxiety, mood, impulsive dyscontrol, delusional, disruptive behavior, and schizophrenic disorders (Widiger & Smith, 2008).

The DSM-IV-TR as a categorical model of classification has a fundamental difficulty in resolving these boundary disputes. The boundaries are quite distinct in theory, yet in reality they appear to be very fluid, arbitrary, and even illusory. The coverage within a diagnostic class literally becomes a territory defended by work group members, fending off threats to their borders, at the same time attempting to annex new territory within their sphere of influence. Clinicians devote considerable amounts of time attempting to make differential diagnoses, and researchers spend time, funds, and journal space arguing whether early-onset dysthymia is a personality disorder or a mood disorder (Huprich, 2003; Ryder, Bagby, & Schuller, 2002; Vachon Sellbom, Ryder, Miller & Bagby, in press). It is perhaps time to recognize that there is no clear answer to such

questions or, minimally, to allow both perspectives comparable representation.

## The Continuum of Depression

Even the namesake for the neo-Kraepelinian approach to diagnosis appears to have known that it doesn't really work. Kraepelin (1917) himself acknowledged that "wherever we try to mark out the frontier between mental health and disease, we find a neutral territory, in which the imperceptible change from the realm of normal life to that of obvious derangement takes place" (p. 295). A simple inspection of the diagnostic criteria for major depressive disorder would not lend confidence to a conceptualization of this disorder as a condition that is qualitatively distinct from normal depression or sadness (Andrews et al., 2008). The diagnostic criteria include depressed mood, loss of interest or pleasure, weight loss (or gain), insomnia (or hypersomnia), psychomotor retardation (or agitation), loss of energy, feelings of worthlessness, and/or diminished capacity to make decisions. Each of these diagnostic criteria is readily placed along a continuum of severity that would shade imperceptibly into what would be considered a normal sadness or depression. DSM-IV-TR, therefore, includes specific thresholds for each of them, but they are clearly arbitrary attempts to demarcate simply a relatively high level of severity (e.g., "nearly every day" or "markedly diminished," and at least a "2-week" period; APA, 2000). The diagnosis itself requires five of the nine criteria, with no apparent rationale for this threshold other than it would appear to be severe enough to be defensible to be titled as a "major" depressive episode, as distinguished from a "minor" depressive episode, which is then distinguished from "normal" sadness (APA, 2000).

Depression does appear to shade imperceptibly into "normal" sadness (Andrews et al., 2008). Ustun and Sartorius (1995) conducted a study of 5,000 primary care attendees in 14 countries and reported a linear relationship between disability and number of depressive symptoms. Kessler, Zhao, Blazer, and Swartz (1997) examined the distribution of minor and major symptoms of depression using data from the National Comorbidity Survey. They examined the relationship of these symptoms with parental history of mental disorder, number and duration of depressive episodes, and comorbidity with other forms of psychopathology. Relationship increased with increasing number of symptoms, with no clear, distinct break in relationships. Sakashita, Slade, and

Andrews (2007) examined the relationship between the number of symptoms of depression and four measures of impairment using data from the Australian National Survey of Mental Health and Well-Being, and found that the relationship was again simply linear, with no clear or natural discontinuity to support the selection of any particular cutoff point.

Taxometrics refers to a series of related statistical techniques to detect whether a set of items is optimally understood as describing (assessing) a dimensional or a categorical construct (Beauchaine, 2007; Ruscio & Ruscio, 2004). Other statistical techniques, such as cluster or factor analyses, presume that the construct is either categorical or dimensional (respectively) and then determines how best to characterize the variables or items in either a categorical or dimensional format (respectively). Taxometric analyses are uniquely intriguing in providing a direct test of which structural model is most valid in characterizing the set of items or variables.

A number of taxometric studies have been conducted on various symptoms and measures of depression. The first was provided by Ruscio and Rusio (2000) in their taxometric analyses of items from the Beck Depression Inventory and, independently, items from the Zung Self-Rating Depression Scale in a sample of 996 male veterans who had received a diagnosis of post-traumatic stress disorder but also had a high prevalence rate of major depressive disorder, as well as a sample of 8,045 individuals (60% female) who completed the items from the Depression scale of the Minnesota Multiphasic Personality Inventory (MMPI). They indicated that "results of both studies, drawing on three widely used measures of depression, corroborated the dimensionality of depression" (Ruscio & Ruscio, 2000, p. 473).

The taxometric findings of Ruscio and Ruscio (2000) have been subsequently replicated, including taxometric analyses of (a) structured interview assessments of DSM-IV-TR major depressive disorder symptoms and, independently, items from the Beck Depression Inventory in a sample of 960 psychiatric outpatients (Slade, 2007); (b) major depressive disorder diagnostic criteria assessed in the 1,933 persons who endorsed at least one criterion in the Australian National Survey of Mental Health and Well-Being (Slade & Andrews, 2005); (c) self- and parent reported depressive symptoms in 845 children and adolescents drawn from the population-based

Georgia Health and Behavior Study (Hankin, Fraley, Lahey, & Waldman, 2005); (d) responses to MMPI-2 depression scales completed by 2,000 psychiatric inpatients and outpatients (Franklin, Strong, & Greene, 2002); (e) epidemiologic survey of depressive symptoms within 392 college students (Baldwin & Shean, 2007); (f) Beck Depression Inventory items reported by 2,260 college students (Ruscio & Ruscio, 2002); and (g) depression items in the Composite International Diagnostic Interview, as administered in the National Comorbidity Survey to 4,577 participants who endorsed the item concerning a lifetime occurrence of sad mood or loss of interest (Prisciandoro & Roberts, 2005). However, in contrast to the findings from these eight taxometric studies, three taxometric studies have supported a latent class taxon, including semistructured interview assessments of DSM-IV-TR major depressive disorder symptoms in 1,800 psychiatric outpatients (Ruscio, Zimmerman, McGlinchey, Chelminski, & Young, 2007), interview and self-report assessments of depression in 1,400 high school students (Solomon, Ruscio, Seeley, & Lewinsohn, 2006), and self-report and interview data on depression in 378 adolescents receiving treatment for depression (Ambrosini, Bennett, Cleland, & Haslam, 2002). In sum, the bulk of the evidence does appear to support a dimensional understanding of depression, but there is some ambiguity and inconsistency in the taxometric findings (Beach & Amir, 2003; Beauchaine, 2007; Widiger, 2001b).

### *Subthreshold Major Depression*

Depression is a section of the diagnostic manual that does have considerable difficulty identifying or defining a clear boundary with "normal" sadness. Subthreshold cases of depression (i.e., persons with depressive symptoms below the threshold for a DSM-IV-TR mental disorder diagnosis) are clearly responsive to pharmacologic interventions, do seek treatment for their sadness, and are often being treated within primary care settings (Judd, Schettler, & Akiskal, 2002; Magruder & Calderone, 2000; Pincus, McQueen, & Elinson, 2003). These facts contributed to the proposal to include within DSM-IV the diagnosis of "minor depressive disorder" for which it is simply acknowledged "can be difficult to distinguish from periods of sadness that are an inherent part of everyday life" (APA, 2000, p. 776).

Wakefield (2007) has been critical of the DSM-IV-TR criteria for major depressive disorder for including an inconsistently applied exclusion criterion. The diagnosis excludes most instances of depressive reactions to the loss of a loved one (i.e., uncomplicated bereavement). Depression after the loss of a loved one can be considered a mental disorder if "the symptoms persist for longer than 2 months" (APA, 2000, p. 356). Allowing just 2 months to grieve before one is diagnosed with a mental disorder does appear to be rather arbitrary. Perhaps more importantly, it is also unclear if depression in response to other losses should not also then be comparably excluded, such as depression secondary to the loss of a job or physical health (Wakefield, Schimtz, First, & Horwitz, 2007).

One could also argue alternatively that all exclusion criteria should be removed. Perhaps the problem is not that depression in response to a loss of a job or physical disorder should not be a disorder, analogous to bereavement (Wakefield, 2007); perhaps the problem is that bereavement should be a mental disorder (Bonanno et al., 2007; Forstmeier & Maercker, 2007; Widiger & Miller, 2008). What is currently considered to be a normal depression in response to the loss of a loved one does often, if not always, include pain and suffering, meaningful impairment to functioning, and is outside of the ability of the bereaved person to fully control, the essential hallmarks of a mental disorder (Widiger & Sankis, 2000). The depression is a reasonable response to the loss of a loved one, but many physical disorders and injuries are reasonable and understandable responses to viruses and accidents. The loss is part of the etiology for the disorder, not a reason for which the disorder is not present (Widiger, 2008).

### Personality Disorders

Rounsaville et al. (2002) suggested that the first section of the APA diagnostic manual to shift to a dimensional classification should be the personality disorders (ignoring for the moment that mental retardation is already dimensional). They did not provide a reason for identifying personality disorders as a likely first place for such a fundamental shift, but one reason would be that personality disorders have been among the most problematic of disorders to be diagnosed categorically (First et al., 2002). Personalities are generally understood to involve constellations of adaptive and maladaptive personality traits that are not well summarized in just one word, the etiologies for which appear to involve complex interactions of an array of genetic dispositions and environmental experiences unfolding over time. The personality disorder diagnostic categories of DSM-IV-TR do not appear to be functioning well as a descriptive model, being stricken with

significant diagnostic heterogeneity, excessive diagnostic co-occurrence, lack of stable or meaningful diagnostic thresholds, inadequate coverage, and a weak scientific foundation (Clark, 2007; Trull & Durrett, 2005; Widiger & Trull, 2007).

However, a more positive reason for personality disorders being potentially the first to shift to a dimensional model of classification is that there already exists a well-developed and empirically supported dimensional classification of general personality structure with which the APA personality disorders can be readily integrated: the five-factor model (Widiger & Trull, 2007). The five-factor model (FFM) consists of five broad domains of general personality functioning: neuroticism (or emotional instability), extraversion versus introversion, openness versus closedness, agreeableness versus antagonism, and conscientiousness. The FFM was derived originally through empirical studies of the trait terms within the English language. Language can be understood as a sedimentary deposit of the observations of persons over the thousands of years of the language's development and transformation. The most important domains of personality functioning are those with the most number of trait terms to describe and differentiate the various manifestations and nuances of a respective domain, and the structure of personality is suggested by the empirical relationships among these trait terms. The initial lexical studies with the English language converged well onto a five-factor structure (Ashton & Lee, 2001). Subsequent lexical studies have been conducted on many additional languages (e.g., German, Dutch, Czech, Polish, Russian, Italian, Spanish, Hebrew, Hungarian, Turkish, Korean, and Filipino), and these have confirmed well the existence of the five broad domains (Ashton & Lee, 2001; Church, 2001). The five broad domains have been differentiated into more specific facets by Costa and McCrae (1992) on the basis of their development of and research with the NEO Personality Inventory-Revised (NEO PI-R), by far the most commonly used and heavily researched measure of the FFM.

Studies have also now well documented that all of the DSM-IV-TR personality disorder symptomatology are readily understood as maladaptive variants of the domains and facets of the FFM (O'Connor, 2002, 2005; Samuel & Widiger, 2008; Saulsman & Page, 2004; Widiger & Costa, 2002). As acknowledged by Livesley (2001b), "all categorical diagnoses of DSM can be accommodated within the five-factor framework" (p. 24). As expressed by Clark

(2007), a long advocate of an alternative three-factor model (Clark, 2005), "the five-factor model of personality is widely accepted as representing the higher-order structure of both normal and abnormal personality traits" (p. 246). Huprich (2003), Ryder et al. (2002), and Vachon et al. (in press) disagree as to the inclusion of depressive personality disorder in DSM-5, but they do agree that it is best understood from the perspective of the FFM.

However, the purpose of an FFM of personality disorder is not simply to describe the diagnostic categories of DSM-IV-TR. It is instead to replace the DSM-IV-TR diagnostic categories with a more clinically useful, feasible, and empirically validated classification. The FFM of personality disorder would cover both normal and abnormal personality functioning within a single, common structure, bringing to an understanding of personality disorders a considerable amount of basic science research supporting behavior genetics (Yamagata et al., 2006), molecular genetics for neuroticism (Munafo, Clark, & Flint, 2005), childhood antecedents (Caspi, Roberts, & Shiner, 2005; Mervielde, De Clerq, De Fruyt, & Van Leeuwen, 2005), temporal stability across the life span (Roberts & DelVecchio, 2000), and universality (Allik, 2005; Ashton & Lee, 2001). This is a scientific foundation that is sorely lacking for the existing nomenclature (Blashfield & Intoccia, 2000; Widiger & Trull, 2007).

Widiger, Costa, and McCrae (2002) proposed a four-step procedure for the diagnosis of a personality disorder from the perspective of the FFM that is quite comparable to the current procedure for the diagnosis of mental retardation. The first step is to obtain a hierarchical and multifactorial description of an individual's general personality structure in terms of the five domains and 30 facets of the FFM. Widiger and Lowe (2007) provide a discussion of optimal instruments for this assessment. The second step is to identify problems in living associated with elevated scores. Problems in living associated with each of the 60 poles of the 30 facets of the FFM are provided in Widiger et al. (2002) and McCrae, Loeckenhoff, and Costa (2005). Each of these problems is considered within the social-cultural context in which the person must function, as some personality traits can be quite adaptive within some contexts but maladaptive within others (Wakefield, 2008; Widiger & Costa, 1994). The third step is to determine whether the impairments reach a clinically significant level that would warrant a diagnosis of personality disorder. This can be done through simply a sum of the impairments associated with

each facet or through a more inferential consideration of the configuration or interaction of traits (Wakefield, 2008). The latter is more consistent with traditional personality disorder theory, but the former would be simpler and perhaps more reliable. The fourth step is optional: a quantitative matching of the individual's FFM personality profile to prototypic profiles of diagnostic constructs (e.g., Miller & Lynam 2003; Trull, Widiger, Lynam, & Costa, 2003). An illustration of this four-step procedure was provided by Widiger and Lowe (2007). Further discussions of this proposal are provided by Widiger and Lowe (2008) and Widiger and Mullins-Sweatt (2009).

The FFM of personality disorder has substantially more construct validity than the existing diagnostic categories (Skodol et al., 2005; Widiger & Trull, 2007). However, an FFM diagnosis might at first blush appear to involve a considerable amount of work (step four is, though, optional). Clinicians may understandably find it daunting to conceive of having to become familiar with both the adaptive and maladaptive variants of all 60 poles of all 30 facets of the FFM (Widiger et al., 2002). A lengthy, complicated profile concerning 60 poles of 30 facets is perhaps unlikely to be used reliably (Ruscio, 2008). Consider, for instance, the original Framingham Index for indexing dimensionally the risk for cardiac problems (Kraemer, 2008). The weighting of age, gender, smoking status, high blood pressure medication, high-density lipoprotein cholesterol, and so forth provided a highly valid measure of cardiac risk but did not become a routine measure in general clinical practice due to being considered overly cumbersome. A simplified version was therefore created and is now frequently used.

Figure 13.1 provides an abbreviated version of the FFM of personality disorder (Widiger & Mullins-Sweatt, 2009; Widiger & Lowe, 2008). The FFM classification of personality disorder provided in Figure 13.1 is a simplification in a number of ways. First, the adaptive behaviors are confined to just the five broad domains, rather than the 30 facets. In addition, the maladaptive facets have been reduced from 60 to just 26. This reduction was achieved in part by eliminating poles of facets that were considered to be too infrequent or obscure for most clinical use (e.g., maladaptively high openness to aesthetics).

Figure 13.2 provides draft diagnostic criteria for the extraversion versus introversion domain, and for the four respective maladaptive facets for that domain included within the abbreviated version. A patient is first assessed with respect to the six facets of the FFM. Each facet is rated on a 1 to 5 Likert scale, consistent with existing research with the Five-Factor Model Rating Form (FFMRF; Mullins-Sweatt, Jamerson, Samuel, Olson, & Widiger, 2006). If the person receives an elevated score, then the clinician would assess for the presence of the two maladaptive variants of high extraversion (i.e., reckless sensation-seeking and intense attachment). If the person receives a low score, then the clinician would assess for maladaptive variants of introversion. Space limitations prohibit the presentation of all of the diagnostic criteria for all five domains and the 26 facets, but these can obtained on request from the first author. If the person receives a score within the middle range, then no further assessment would typically be necessary (exceptions to this are discussed below).

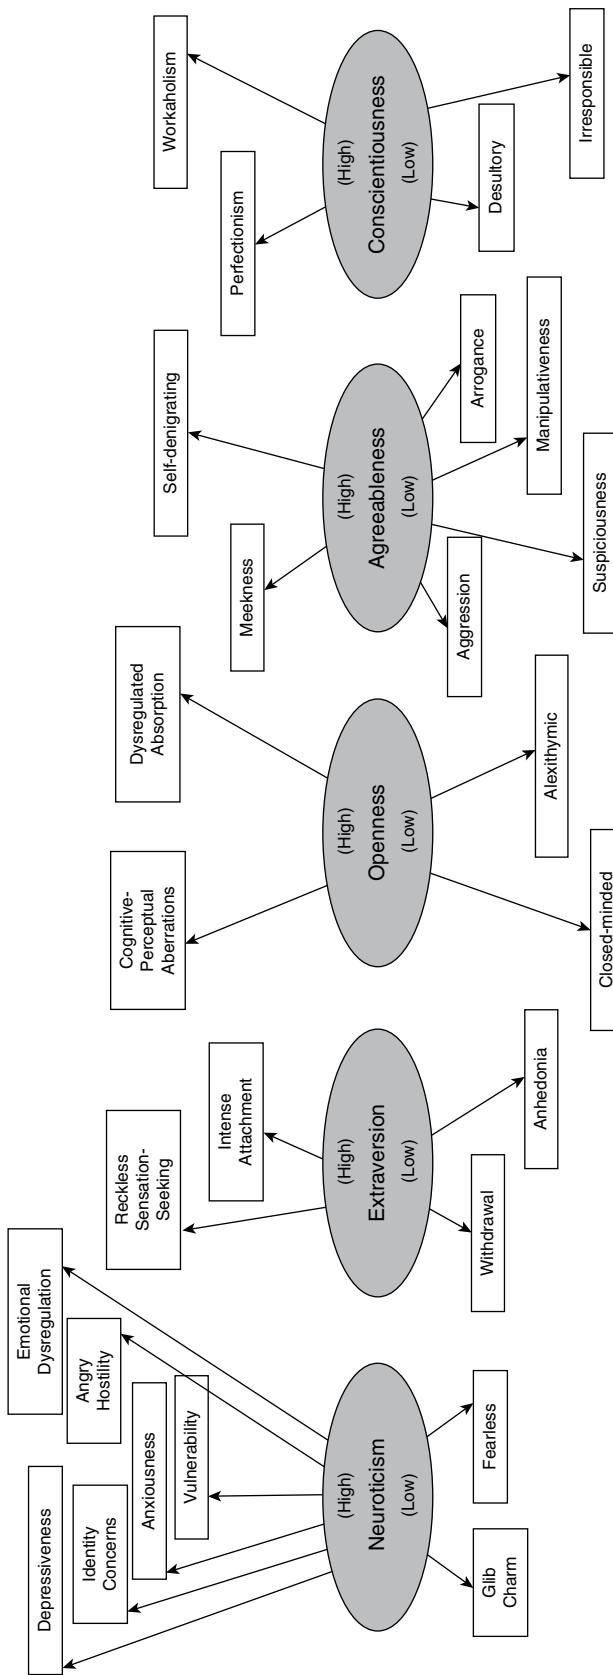
The presence of 26 facets might still seem daunting. However, it is important to appreciate that each of the FFM clinical constructs are substantially easier to assess than the DSM-IV-TR personality disorders, as the latter constitute complex combinations and constellations of these constructs (Clark, 2007; Livesley, 2001b; Lynam & Widiger, 2001; Widiger & Trull, 2007). A classification system that abandons the fruitless effort to make illusory differential diagnoses among overlapping diagnostic categories in favor of a more straightforward description of each individual's unique personality profile will likely be much easier to use than the existing diagnostic categories (Widiger & Lowe, 2007). In addition, the maladaptive facets are only assessed if there is an elevation on a respective domain. One first begins with the description of the person in terms of general personality functioning at the level of the five broad domains. If the person is assessed to be high in agreeableness (for instance), one would then assess for the maladaptive variants of deference and meekness, and one would not need to assess for the maladaptive variants of suspiciousness, manipulation, aggression, or arrogance. In this way, the five broad domains serve in part as a screening process, identifying whether particular maladaptive traits need to be assessed (exceptions to this rule of thumb can occur if a person is both extremely high and extremely low on facets within the same domain). An FFM assessment of personality disorder generally takes half the amount of time than an assessment of the DSM-IV-TR personality disorders, as much of the administration of a DSM-IV-TR personality disorder semistructured interview is spent in the assessment of diagnostic criteria that are not present (Widiger & Lowe, 2007). This considerable amount of time is diminished substantially by the


**Figure 13.1** Abbreviated Version of FFM Proposal for DSM-5
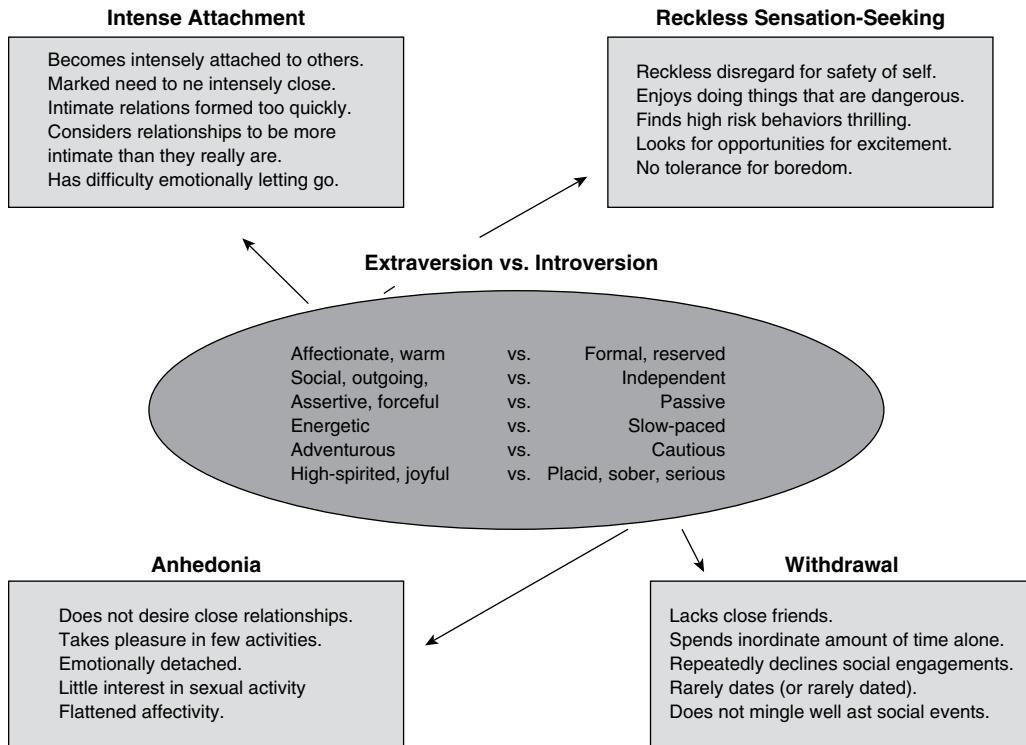

**Figure 13.2** FFM Diagnosis of Maladaptive Extraversion Versus Introversion

FFM through the screening process of assessing whether the person is high or low in the five broad domains of general personality functioning.

The abbreviated version does naturally fail to include all of the maladaptive traits present within the FFM (Widiger et al., 2002; Widiger & Lowe, 2008). Missing from the abbreviated version, for instance, are such maladaptive variants as attention-seeking (high gregariousness), gullibility (high trust), guilelessness (high straightforwardness), exploitativeness and greed (low altruism), callousness (high tough-mindedness), ruminative indecisiveness (high deliberation), hedonism (low self-discipline), and aimlessness (low achievement-striving). Nevertheless, even in the abbreviated version, clinicians would be alerted to the potential presence of the additional maladaptivity through elevations on specifically relevant facet scales within each of the five domains. For example, with respect to Figure 13.2, a person could receive the highest (or lowest) possible score on a respective facet for which no maladaptive variant is provided (e.g., a score of 5 on gregariousness, suggesting the potential presence of attention-seeking, or a score of 1 on warmth suggesting the possibility of interpersonal coldness). These specific facets of

maladaptive personality functioning could then be assessed, if wished, through an implementation of the more complete, full version of the FFM of personality disorder. A number of instruments have been developed to facilitate this more complete and comprehensive assessment (Widiger & Lowe, 2007), including the NEO PI-R (Costa & McCrae, 1992), which will assess well the normal range, as well as the Structured Interview Assessment of the Five-Factor Model (Trull & Widiger, 1997) and the FFMRF (Mullins-Sweatt et al., 2006).

## Discussion

The diagnosis of mental disorders has been largely within the domain of medicine, which has used since the days of Hippocrates a categorical model of classification (Kendell, 1975). Many clinicians identify themselves as being within a branch of medicine, treating pathologies that are qualitatively distinct from normal functioning. A reformulation of mental disorders as shading imperceptibly into normal psychological functioning could complicate the perceived identity of the profession (Guze, 1978; Guze & Helzer, 1987). This concern has perhaps been best expressed by Wakefield (2008), when he raised

a foreboding alarm that a shift to a dimensional classification of personality disorder "has the potential to undermine some of the progress that has been made in relegitimizing psychiatry after the disastrous years of the antipsychiatry movement" (p. 383). One might ask, though, what in fact he is defending. As expressed by Drs. Kupfer, First, and Regier (two of whom are the Chair and Vice Chair of DSM-5):

> In the more than 30 years since the introduction of the Feighner criteria by Robins and Guze, which eventually led to DSM-III, the goal of validating these syndromes and discovering common etiologies has remained elusive. Despite many proposed candidates, not one laboratory marker has been found to be specific in identifying any of the DSM-defined syndromes. Epidemiologic and clinical studies have shown extremely high rates of comorbidities among the disorders, undermining the hypothesis that the syndromes represent distinct etiologies. Furthermore, epidemiologic studies have shown a high degree of short-term diagnostic instability for many disorders. With regard to treatment, lack of treatment specificity is the rule rather than the exception.
> (*Kupfer, First, & Regier*, 2002, p. xviii)

A much greater threat to the credibility of the profession perhaps is the perpetuation of an inherently flawed and failing diagnostic system that continues to try to impose a tradition that is simply inadequate to the task at hand. The diagnostic system is currently failing in many ways, including an absence of a provision of reliably distinct boundaries, an absence of a credible rationale for diagnostic thresholds, an inadequate coverage of existing clinical populations, and the absence of specific etiologies and treatments (Kupfer et al., 2002; Regier et al., 1998; Widiger & Trull, 2007).

Kraemer, Noda, and O'Hara (2004) argue that "a categorical diagnosis is necessary" (p. 21). "Clinicians who must decide whether to treat or not treat a patient, to hospitalize or not, to treat a patient with a drug or with psychotherapy, or what type, must inevitably use a categorical approach to diagnosis" (Kraemer et al., 2004, p. 12). This is not actually correct. In many of these common clinical situations, the decision is not in fact categorical in nature, as there is usually a decision of degree of medication dosage, frequency of therapy sessions, and even degree of hospitalization (e.g., day hospital, partial hospitalization, residential program, and traditional hospitalization). Even more importantly, it is evident that these many different clinical decisions

will not be well informed by a categorical diagnosis, particularly if one considers as well other important social and professional decisions (e.g., disability and insurance coverage). A dimensional model would likely increase the credibility of mental disorder classification by providing the means with which to identify more explicitly and reliably precise points along respective continua that would be optimal for these different decisions, rather than assuming that a single diagnostic threshold—that is itself largely arbitrary—is optimal for all of the different decisions that must be made. The current diagnostic thresholds are not set at a point that is optimal for any particular social and clinical decision, and yet are used to inform most to all of them (Regier & Narrow, 2002). A diagnostic system with the flexibility to set different thresholds for alternative social and clinical decisions could indeed be considerably more useful and credible than the current system. The credibility of the profession is being undermined most by the problems and errors generated by a model that claims to carve psychological or neurochemical functioning at discrete joints but yet clearly fails to do so. A dimensional model of classification could be preferable to governmental, social, and professional agencies because it would provide more reliable, valid, and explicitly defined bases for making important social and clinical decisions.

It is stated in the first paragraph of the introduction to DSM-IV-TR that "our highest priority has been to provide a helpful guide to clinical practice" (APA, 2000, p. xxiii). As First (2005) argued in his rejoinder to proposals for shifting the diagnostic manual into a dimension model, "the most important obstacle standing in the way of its implementation in DSM-5 (and beyond) is questions about clinical utility" (p. 561). Nevertheless, one must again question whether the existing diagnostic manual has appreciable clinical utility. "Apologists for categorical diagnoses argue that the system has clinical utility being easy to use and valuable in formulating cases and planning treatment [but] there is little evidence for these assertions" (Livesley, 2001a, p. 278). First (2005) suggested in one context that "the current categorical system of DSM has clinical utility with regard to the treatment of individuals" (p. 562), yet within another context stated that "with regard to treatment, lack of treatment specificity is the rule rather than the exception" (Kupfer, First, & Regier, 2002, p. xviii). The heterogeneity of diagnostic membership, the lack of precision in description, the excessive diagnostic co-occurrence, the failure to lead to a specific diagnosis, the reliance on the "not

otherwise specified" wastebasket diagnosis, and the unstable and arbitrary diagnostic boundaries of the DSM-IV-TR diagnostic categories (Clark, 2007; Trull & Durrett, 2005; Widiger & Trull, 2007), are matters of clinical utility that present a source of considerable frustration for clinicians.

Consider, for example, the personality disorder diagnoses. It is telling that it has been over 10 years since the American Psychiatric Association has been publishing practice guidelines for the diagnostic categories of DSM-IV-TR and, as yet, treatment guidelines have been developed for only one of the ten personality disorder diagnostic categories (i.e., APA, 2001). The reason is perhaps straightforward: there have been no adequate empirical studies on the treatment of (for instance) the avoidant, schizoid, paranoid, histrionic, narcissistic, obsessive-compulsive, or dependent personality disorders. It would be difficult to even find researchers attempting to develop manualized treatment programs for these personality disorders. One reason is perhaps because the DSM-IV-TR personality disorders are generally not well suited for specific and explicit treatment manuals, as each disorder involves a complex constellation of an array of maladaptive personality traits. Persons meeting the diagnostic criteria for the same personality disorder may not even share many of the same traits (Trull & Durrett, 2005).

What is evident from the personality disorder treatment research is that treatment does not address or focus on the entire personality structure (Paris, 2006). Clinicians treat, for instance, the affective instability, the behavioral dyscontrol, or the self-mutilation of persons diagnosed with borderline personality disorder, which are specific facets of the FFM of personality disorder (see Figure 13.1). Effective change occurs with respect to these components, rather than to the entire, global construct. One of the empirically supported treatments for borderline personality disorder (APA, 2001) is dialectical behavior therapy (DBT). Research has demonstrated that DBT is an effective treatment for many of the components of this personality disorder, but it is evident to even the proponents of this clinical approach that the treatment is not entirely comprehensive in its effectiveness (Linehan, 2000). DBT has been particularly effective with respect to decreasing self-harm and angry hostility, but not with other aspects of borderline psychopathology, such as hopelessness (Scheel, 2000), components readily identified in the FFM of personality disorder. It is difficult to imagine clinicians not finding useful a classification system that concerns explicitly their focus of treatment, such as cognitive-perceptual aberrations, anxiousness, emotional dysregulation, intense attachment, meekness, or workaholism (see Figure 13.1).

The factor analytic development of the FFM provides a more conceptually (as well as empirically) coherent structure than the syndromal constellations of traits within DSM-IV-TR (Lynam & Widiger, 2001). Extraversion and agreeableness are domains of interpersonal relatedness, neuroticism is a domain of emotional instability and dysregulation, conscientiousness is a domain of work-related behavior and responsibility, and openness is a domain of cognitive intellect, curiosity, and creativity (Costa & McCrae, 1992; Mullins-Sweatt & Widiger, 2006). Extraversion and agreeableness are confined specifically to social, interpersonal dysfunction, an area of functioning that is relevant to relationship quality both outside and within the therapy office. Interpersonal models of therapy, marital-family therapy, and group therapy would be confined largely to these two domains, or at least they would have the most specific and explicit implications for this domain. In contrast, neuroticism provides information with respect to mood, anxiety, and emotional dyscontrol, often targets for pharmacologic interventions (as well as cognitive, behavioral, and psychodynamic interventions). There are very clear pharmacologic implications for mood and anxiety dysregulation and emotional instability (e.g., anxiolytic, antidepressants, and/or mood stabilizers), but little to none for maladaptive antagonism or introversion, the interpersonal domains of the FFM. Maladaptively high openness implies cognitive–perceptual aberrations, which would have pharmacologic implications (i.e., neuroleptics) that are quite different from those of neuroticism. The domain of conscientiousness is, in contrast to agreeableness and extraversion, the domain of most specific relevance to occupational dysfunction, or impairments concerning work and career. Maladaptively high levels involve workaholism, perfectionism, and compulsivity; low levels involve laxness, negligence, and irresponsibility. There might be specific pharmacologic treatment implications for low conscientiousness (e.g., methylphenidates) although, as yet, none for maladaptively high conscientiousness. Perhaps there never will be a pharmacotherapy for high conscientiousness, but the point is that the structure of the FFM is commensurate with much more specific treatment implications than the existing diagnostic categories. Empirical support for the perceived utility of the

FFM relative to DSM-IV-TR for treatment decisions (and other matters of clinical utility) is provided in studies by Samuel and Widiger (2006) and Lowe and Widiger (2009).

## Conclusion

Most (if not all) mental disorders appear to be the result of a complex interaction of an array of interacting biological vulnerabilities and dispositions with a number of significant environmental, psychosocial events that often exert their effects over a progressively developing period of time (Rutter, 2003). The symptoms and pathologies of mental disorders appear to be highly responsive to a wide variety of neurobiological, interpersonal, cognitive, and other mediating and moderating variables that help to develop, shape, and form a particular individual's psychopathology profile. This complex etiological history and individual psychopathology profile are unlikely to be well described by single diagnostic categories that attempt to make distinctions at nonexistent discrete joints along the continuous distributions (Widiger & Samuel, 2005). The publication of DSM-III provided a significant, major advance in the diagnosis and classification of psychopathology (Klerman, 1983). As Craddock and Owen (2002) suggest, perhaps it is time to move on.

The Robins and Guze (1970) paradigm for the validation of categorical diagnosis has been widely influential within psychiatry (Klerman, 1983; Kupfer et al., 2002; Spitzer, Endicott, & Robins, 1975; Spitzer et al., 1978). In 1989, L. Robins and Barrett (1989) edited a text in honor of this classic paper. Kendell (1989) provided the final word in his closing chapter. His conclusions, however, were curiously negative. "Ninety years have now elapsed since Kraepelin first provided the framework of a plausible classification of mental disorders. Why then, with so many potential validators available, have we made so little progress since that time?" (Kendell, 1989, p. 313). He answered his rhetorical question in the next paragraph: "One important possibility is that the discrete clusters of psychiatric symptoms we are trying to delineate do not actually exist but are as much a mirage as discrete personality types" (Kendell, 1989, p. 313).

Work is now beginning on DSM-5, and it is evident that a primary goal is to shift the manual toward a dimensional classification (Helzer, Wittchen, Krueger, & Kraemer, 2008). Nevertheless, it also appears to be the case that the shifts likely to be taken in

DSM-5 will neither be fundamental nor significant. The effort is likely to fall considerably short of a true paradigm shift. Current proposals appear, for the most part, to be quite tentative, if not timid. "What is being proposed for DSM-5 is not to substitute dimensional scales for categorical diagnoses, but to add a dimensional option to the usual categorical diagnoses for DSM-5" (Kraemer, 2008, p. 9).

As acknowledged by Helzer, Kraemer, and Krueger (2006) "our proposal not only preserves categorical definitions but also does not alter the process by which these definitions would be developed. Those charged with developing criteria for specific mental disorders would operate just as their predecessors have" (p. 1675). In other words, work groups will continue to develop diagnostic criteria to describe prototypic cases in a manner that will maximize homogeneity (Robins & Guze, 1970; Spitzer et al., 1980), thereby continuing to fail to adequately describe typical cases and again leaving many patients to receive the diagnosis of NOS.

Dimensional proposals for DSM-5 were presented in a conference sponsored by the APA and NIMH that was the capstone to ten earlier conferences devoted to identifying "the future of psychiatric diagnosis" (Regier, 2008, p. xvii). The purpose of the conference was to present "a set of suggestions for developing dimensional alternatives for DSM-5 categorical diagnoses" (Helzer, Wittchen, et al., 2008, p. 116). In the end, however, the proposals were to construct "supplementary dimensional approaches to the categorical definitions that would also relate back to the categorical definitions in an unambiguous way" (Helzer, Wittchen, et al., 2008, p. 116). The proposals were confined simply to constructing a standardized quantitative dimensional assessment rating system for severity of substance use disorders (Helzer, Bucholz, & Gossop, 2008), a supplementary dimensional measure of depression to aid in the identification of major depressive disorder and facilitate assessment of treatment response (Andrews et al., 2008), the identification of dimensions of psychotic symptomatology (e.g., positive symptoms, negative symptoms, and disorganization) to be used in conjunction with the categorical diagnoses (Allardyce, Suppes, & Os, 2008), adding cross-cutting dimensions and stages of disorder that would supplement the assessment of the anxiety disorder diagnostic categories (Shear, Bjelland, Beesdo, Gloster, & Wittchen, 2008), and supplementary dimensional scales to assist in the assessment of the existing categorical diagnoses of childhood (Hudziak, Achenbach,

Althoff, & Pine, 2008). All DSM-5 work groups will be asked to "proceed as they always have in creating the phenomenological definitions for DSM" (Helzer, Wittchen, et al., 2008, p. 123) but to also indicate, if possible, how each respective diagnostic category can be rated on a scale of severity (it is perhaps worth noting that DSM-IV-TR already includes a method for rating the severity of each disorder: APA, 2000, p. 2). In sum, "what is being proposed for DSM-5 is not to substitute dimensional scales for categorical diagnoses, but to add a dimensional option to the usual categorical diagnoses for DSM-5" (Kraemer, 2008, p. 9).

DSM-III was highly innovative in many important respects (Kendell, 1983; Klerman, 1983; Spitzer, Williams, & Skodol, 1980). It would appear that the same innovative vision may fail to occur for DSM-5. The difficulty is evident in part by two caveats outlined by Kraemer (2008). She stated that "to achieve what is hoped from [the] addition of a dimensional diagnosis into DSM-5, there are certain criteria that would have to be met" (p. 14). The first criterion is that "it is crucial that a DSM-5 dimensional diagnosis correspond well with its categorical diagnosis" (p. 14). The second was that "the dimensional diagnosis … must show good … clinical validity, and withstand more demanding challenges to validity" (p. 15). These would not appear to be particularly compatible goals, as the existing diagnostic categories have already been shown to be grossly inadequate with respect to clinical validity and withstanding challenges to their validity (Kupfer et al., 2002).

This is perhaps most clearly evident with respect to the personality disorders. The most likely shift in the official classification of personality disorders is to provide a dimensional profile in terms of the existing (or somewhat revised) diagnostic categories (Oldham & Skodol, 2000). A personality disorder would be characterized as prototypic if all of the diagnostic criteria are met, moderately present if one or two criteria beyond the threshold are present, threshold if the patient just barely meets the diagnostic threshold, subthreshold if symptoms are present but are just below diagnostic threshold, traits if no more than one to three symptoms are present, and absent if no diagnostic criteria are present. This proposal was in fact made for DSM-IV (Widiger, 1996) but, at the time, it was considered to be too radical of a shift (Gunderson, 1998).

A fundamental limitation of this revision is that clinicians would continue to be describing patients in terms of markedly heterogeneous and overlapping constructs. A profile description of a patient in terms

of the antisocial, borderline, dependent, histrionic, and other DSM-IV (or DSM-5) constructs would essentially reify the excessive diagnostic co-occurrence that is currently being obtained (Clark, 2007; Trull & Durrett, 2005; Widiger & Mullins-Sweatt, 2005). In other words, the problem of excessive diagnostic co-occurrence would not in fact be solved. It would simply be accepted as an inherent limitation of the diagnostic manual. This is comparable to the decision made by the authors of DSM-III-R (APA, 1987) to address the problematic heterogeneity of the diagnostic categories by abandoning monothetic criterion sets that required homogeneity and converting to polythetic criterion sets that accepted the existence of the problematic heterogeneity (Widiger, Frances, Spitzer, & Williams, 1988).

It is likely that a more significant, meaningful, and valid shift in the classification of personality disorders will be included in an appendix to DSM-5, analogous to the alternative dimensional classification of psychosis already included in an appendix to DSM-IV-TR (APA, 2000, p. 765). However, it may not involve an integration of the classification of personality disorders with the dimensional classification of FFM personality structure. The proposal, to date, is confined simply to a reorganization of personality disorder symptomatology in terms of four broad domains (Krueger, Skodol, Livesley, Shrout, & Huang, 2008). These four broad domains can be coordinated with four of the five domains of the FFM (Widiger, 1998), but there was no effort to make this connection within the published proposal. In fact, the proposal for DSM-5 was distinguished from the FFM proposal (Krueger et al., 2008).

DSM-III is often said to have provided a significant paradigm shift in how psychopathology is diagnosed (Kendell & Jablensky, 2003; Klerman, 1983; Regier, 2008). Much of the credit for the innovative nature and success of DSM-III is due to the foresight, resolve, and perhaps even courage of its Chair, Dr. Robert Spitzer. The authors of DSM-5 have the empirical support and the opportunity to lead the field of psychiatry to a comparably bold new future in diagnosis and classification.

***Future Directions***
• How would a future edition of the diagnostic manual be reorganized dimensionally? This reorganization should be comprehensive, covering all of the existing categorical diagnoses (or more accurately the symptoms covered by each respective diagnosis) currently included within the diagnostic manual (e.g., psychotic disorders, mental

retardation, mood disorders, sexual dysfunctions, and so forth).

• How should each section of the diagnostic manual (e.g., mood disorders, anxiety disorders, sexual dysfunctions, dissociative disorders) be optimally reorganized dimensionally? This reorganization would operate under the questionable assumption that a dimensional restructure of psychopathology would retain the existing sections.

• What would be the optimal diagnostic thresholds on each respective dimension for different clinical and social decisions? This would most likely be based on level of impairment and need for professional services.

## Acknowledgment

The authors express their appreciation to Sara Boyd and Greg Smith for their comments on earlier draft.

## Abstract

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) has undergone considerable revisions since its first publication, with a continuous increase in the number of the anxiety and mood disorder categories. However, many researchers have expressed concern that the expansion of our nosology has resulted in less consideration of the overlapping features of emotional disorders. The purpose of this chapter is to review current issues and empirical evidence pertinent to the classification of anxiety and mood disorders and the relevance of these issues to treatment planning. It discusses discriminant validity, including diagnostic reliability and comorbidity, reviews the existing hierarchical models of emotional disorders, proposes a dimensional approach for classification of anxiety and mood disorders, and reviews transdiagnostic treatments of emotional disorders.

**Key Words:** Anxiety disorders, assessment, comorbidity, diagnostic reliability, dimensional classification, hierarchical models, mood disorders, overlap, transdiagnostic treatment

The *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*) has undergone considerable revisions since its first publication, with a continuous increase in the number of the anxiety and mood disorder categories. The fourth edition of the *DSM* (*DSM-IV*; American Psychiatric Association [APA], 1994) specifies 12 anxiety disorder categories and ten mood disorder categories. The anxiety disorders are panic disorder, panic disorder with agoraphobia (PDA), agoraphobia without a history of panic disorder, social phobia, specific phobia, generalized anxiety disorder (GAD), obsessive-compulsive disorder (OCD), post-traumatic stress disorder (PTSD), acute stress disorder, anxiety disorder due to a general medical condition, substance-induced anxiety disorder, and anxiety disorder not otherwise specified (NOS). A 13th category, mixed anxiety-depressive disorder, was considered for inclusion in *DSM-IV*, but it is currently included in the appendix of disorders in need of further study for *DSM-5* (cf. Zinbarg et al., 1994). The mood disorder categories includes major depressive disorder (MDD), dysthymic disorder, depressive disorder NOS, bipolar I and bipolar II disorders, bipolar disorder NOS, cyclothymic disorder, mood disorder due to a general medical condition, substance-induced mood disorder, and mood disorder NOS. Table 14.1 summarizes key diagnostic features for major anxiety and mood disorders.

This increase could be due to expansion of knowledge of the nature of psychopathology and classification of disorders. However, many researchers (e.g., Andrews, 1996; Brown & Barlow, 2002; Tyrer, 1989) have expressed concern that the expansion of our nosology has resulted in less consideration of the overlapping features of emotional disorders, which may have more significance in explaining their etiology, course, and treatment response than the "unique" features of specific disorders. In fact, many anxiety disorders share fundamental processes, such as apprehension of situations or objects, and differ mostly in content of apprehension (e.g., worry about

**Table 14.1 Overview of key features of major anxiety and depressive disorders in *DSM-IV***

| Disorder | Key feature(s) |
|---|---|
| Panic Disorder | Recurrent, unexpected panic attacks and persistent worry/concern about additional attacks or their consequences |
| Panic Disorder with Agoraphobia | Meets criteria for panic disorder<br>Agoraphobia: fear/avoidance of situations where panic attacks might occur |
| Social Phobia | Marked fear/avoidance of social situations due to possibility of embarrassment or humiliation |
| Specific Phobia | Marked fear/avoidance of specific objects or situations (e.g., animals, heights, receiving injections) |
| Generalized Anxiety Disorder | Chronic excessive, uncontrollable worry about a number of events or activities (e.g., job performance, finances) |
| Obsessive-Compulsive Disorder | Recurrent, intrusive thoughts, images or impulses (e.g., excessive doubting, thoughts of contamination) |
| Posttraumatic Stress Disorder | Persistent reexperiencing (e.g., dreams), distress, and avoidance of stimuli associated with prior exposure to extreme stress (e.g., combat) |
| Acute Stress Disorder | Short-term reexperiencing, dissociation, distress, and avoidance of stimuli associated with exposure to extreme stress |
| Major Depressive Disorder | At least one 2-week episode of persistent depressed mood or loss of interest |
| Dysthymic Disorder | Persistent depressed mood for at least 2 years |
| Bipolar I Disorder | Occurrence of a manic episode characterized by at least 1-week period of persistent expansive mood or a mixed episode, characterized by 1 week of both mania and major depression symptoms, and major depressive episodes |
| Bipolar II Disorder | At least one major depressive episode and at least one hypomanic episode, characterized by at least a 4-day period of persistent expansive mood |
| Cyclothymic Disorder | At least 2 years of multiple periods of hypomanic symptoms and periods of depressive symptoms |

*DSM-IV = Diagnostic and statistical manual of mental disorders, 4th edition* (APA, 1994).

contamination in OCD, worry about several events or activities in GAD). The question arises whether these manifestations are sufficiently distinct to warrant separate diagnostic categories. The purpose of this chapter is to review current issues and empirical evidence pertinent to the classification of anxiety and mood disorders and the relevance of these issues to treatment planning.

Indeed, a great deal of evidence has led to questioning the discriminant validity of the anxiety and depressive disorder categories. Findings of unfavorable inter-rater agreement (diagnostic reliability) and a high degree of covariance between anxiety and mood disorders at diagnostic, symptom, and genetic levels (e.g., Brown, Campbell, Lehman, Grisham, & Mancill, 2001; Hettema, Neale, & Kendler, 2001) have been cited in support of these concerns.

## Diagnostic Reliability

With the increase in specificity and complexity of diagnostic criteria for anxiety and mood disorders, the use of standardized diagnostic measures became more important. Such instruments are essential for establishing the reliability of diagnostic categories. Several instruments have been developed, including the Structured Clinical Interview for *DSM-IV* Axis I disorders (SCID-I; First, Spitzer, Gibbon, & Williams, 1997) and the Schedule for Affective Disorders and Schizophrenia – Lifetime Anxiety Version (SADS-LA; Fyer, Endicott, Mannuzza, & Klein, 1985). However, these and some other structured diagnostic interviews do not cover sufficient information to allow for making differential diagnoses among anxiety and mood disorders. For example, the SCID-I and SADS-LA are useful for screening for a broad range of psychopathology, but they collect the minimum

amount of information necessary for each of the *DSM-IV* disorders, in the interest of time. Therefore, these instruments are not as valuable for the purposes of detailed inquiry into anxiety and depressive disorders.

### Anxiety Disorders Interview Schedule

The first edition of the Anxiety Disorder Interview Schedule (ADIS; Di Nardo, O'Brien, Barlow, Waddell, & Blanchard, 1983) was developed specifically for anxiety disorders, to advance research on their classification. It was revised several times, using the experience and revisions of the *DSM*. In 1988, the Anxiety Disorders Interview Schedule – Revised (ADIS-R) was published, corresponding to *DSM-III-R*, to include all anxiety and mood disorders and selected somatoform disorders (Di Nardo & Barlow, 1988). The current version, the Anxiety Disorders Interview Schedule for *DSM-IV*: Lifetime Version (ADIS-IV-L), was published in 1994 to correspond to *DSM-IV* criteria. Unlike its predecessors, the ADIS-IV-L (Di Nardo, Brown, & Barlow, 1994) also included assessment of lifetime disorders, as well as a diagnostic timeline to facilitate the determination of the onset, remission, and temporal sequence of these conditions. It additionally included assessment of substance and alcohol use disorders, as well as a dimensional assessment of the key and associated features of disorders, regardless of whether they meet the criteria for a particular *DSM-IV* diagnosis. These ratings can serve in research on treatment outcome and as dimensional indicators in studies of latent structure (e.g., Brown, 2007). These ratings are also in agreement with the position that it may be more informative to classify features of emotional disorders on a continuum rather than in a categorical fashion (Brown & Barlow, 2005). For each current and lifetime diagnosis, ADIS-IV-L interviewers assign a clinical severity rating from 0 to 8, to indicate the degree of distress and impairment associated with the disorder. A principal diagnosis is assigned to reflect the disorder that causes most impairment and distress.

### Reliability Studies

Diagnostic reliability refers to the extent to which two (or more) independent interviewers agree on the presence or absence of a given diagnosis. The approach to studying diagnostic reliability of the anxiety and mood disorders usually has utilized one of two methods—test–retest or simultaneous—both involving the use of structured clinical interviews such as the ADIS-IV-L (Di Nardo et al., 1994).

Test–retest involves the patient being interviewed by different independent evaluators on two separate occasions (e.g., Brown, Di Nardo, Lehman, & Campbell, 2001; Di Nardo, Moras, Barlow, Rapee, & Brown, 1993). The simultaneous method suggests that a diagnostic interview is video- or audio-taped and rated by an independent evaluator (e.g., Riskind, Beck, Berhick, Brown, & Steer, 1987). In both approaches, the most widely used index of inter-rater agreement is the κ *statistic* (Fleiss, Nee, & Landis, 1979), which ranges in value from 0 (poor agreement) to 1 (perfect agreement). The strategy of interviewing patients on separate occasions is the more stringent approach to estimating diagnostic reliability because it introduces several potential sources of disagreement not found in the single-interview method (e.g., variation in patient report, change in clinical status). The single-interview method also has been criticized for its potential of providing an overly optimistic estimation of diagnostic reliability (e.g., the independent evaluator's judgments may be strongly influenced by the nature and extent of follow-up questions asked by the initial interviewer).

Large-scale reliability studies based on *DSM-III-R* and *DSM-IV* definitions of anxiety and mood disorder categories have indicated that these diagnoses are associated with differential levels of agreement (Brown, Di Nardo, et al., 2001; Di Nardo et al., 1993; Mannuzza et al., 1989; Williams et al., 1992). Results of one large-scale study of the *DSM-IV* anxiety disorders and three of the *DSM-III-R* anxiety and mood disorders are summarized in Table 14.2 for current diagnoses. All four studies employed the test–retest method, but differed on the structured interview used; Brown, Di Nardo, et al. (2001) used the ADIS-IV-L; Di Nardo et al. (1993) used the ADIS-R; Mannuzza et al. (1989) used the SADS-LA, and Williams et al. (1992) used the Structured Clinical Interview for *DSM-III-R* Axis I. The following guidelines were used in the interpretation of κ: κ > .75 = excellent agreement; κ between .60 and .74 = good agreement; κ between .40 and .59 = fair agreement; κ < .40 = poor agreement (Shrout, Spitzer, & Fleiss, 1987), indicating that panic disorder with agoraphobia, social phobia, specific phobia, OCD, and GAD had good to excellent reliability in the *DSM-IV* study (Brown, Di Nardo, et al., 2001). However, certain categories (e.g., MDD, dysthymia) were associated with fair or poor agreement. The reliability of GAD improved in the *DSM-IV* study in comparison to the previous studies, which is probably due to the revision of its

criteria in *DSM-IV*, including the addition of the criterion of uncontrollable worry, specification of worries across "a number of events/activities" as opposed to "at least two worry spheres," and the reduction of the associated symptoms from 18 to six (APA, 1987, 1994). The inter-rater agreement for dysthymia remained poor across the studies.

The factors contributing to unreliability have varied substantially across the anxiety and mood disorders. For example, in the study by Brown, Di Nardo, et al. (2001), the majority of discrepancy involving social phobia, specific phobia, and OCD (62%–67%) resulted from interviewer disagreement on whether the disorder should be rated at a clinical or subclinical level. This, however, was a relatively rare source of disagreement for GAD, MDD, and dysthymia. The most common reason for disagreements across studies has been "information variance" (patients providing different information to the two interviewers), which accounted for 22%–100% of the discrepancies in the Brown, Di Nardo, et al. (2001) study.

The frequency with which other disorders were involved in diagnostic disagreements varied across categories (Brown, Di Nardo, et al., 2001). Disagreement was rather frequent for disorders with overlapping definitional criteria, such as dysthymia, GAD, and MDD (64%–74%). For GAD, 63% of disagreements involving another disorder were with mood disorders. It was also frequent for anxiety and depressive disorders NOS. In the presence of two or more potential diagnoses, the risk for disagreement is increased by the fact that interviewers may not agree as to whether the features of one disorder should be subsumed under another disorder. Indeed, this source of diagnostic disagreement is related to another issue concerning the potentially poor discriminant validity among emotional disorders—their high rate of comorbidity.

## Comorbidity

Consistent evidence of high comorbidity among anxiety and mood disorders is frequently cited to question the distinguishability of the emotional disorders (Andrews, 1990; Brown & Barlow, 2002). Comorbidity studies based on *DSM-III-R* criteria have demonstrated that at least 50% of patients with a principal anxiety disorder have one or more additional diagnoses at the time of assessment (e.g., Brown & Barlow, 1992; Kessler et al., 1994). Similar findings were obtained in a large-scale study ($N = 1,127$) of the *DSM-IV* categories, with patients presenting to an anxiety disorders specialty clinic (Table 14.2; Brown, Campbell, et al., 2001). The nature of exclusion and inclusion criteria for this study (e.g., active substance use disorders and

presence of suicidality were exclusion criteria) and its outpatient setting, similar to previous studies, limited its generalizability and probably rendered conservative estimates of diagnostic co-occurrence. Nevertheless, comorbidity rates for many categories were quite high. Similar to earlier findings, 55% of patients with a principal anxiety or mood disorder had at least one additional anxiety or depressive disorder at the time of the assessment. This rate increased to 76% for lifetime diagnoses. The principal diagnoses of PTSD, MDD, dysthymia, and GAD had the highest comorbidity rates. The lowest comorbidity rates were found for the principal diagnosis of specific phobia. The most commonly occurring additional diagnoses were social phobia (22%) and MDD (20%).

However, the findings of comorbidity alone do not have substantial implications for establishing or refuting the discriminant validity of the emotional disorder constructs. There are multiple conceptual explanations for diagnostic comorbidity (e.g., Andrews, 1996; Brown & Barlow, 2002; Frances, Widiger, & Fyer, 1990). Accounts for comorbidity that challenge current *DSM* classification system include the possibility that disorders co-occur in part because they share overlapping definitional criteria, or that they represent variations of a broader underlying syndrome that has been erroneously separated by the classification system. For example, in regard to the first explanation, the associated symptom criteria for *DSM-IV* GAD diagnosis almost entirely overlap with those of major depression and dysthymia (e.g., sleep disturbance, fatigue, concentration difficulties, restlessness). In fact, this overlap contributed to findings of an exceptionally high comorbidity rate of GAD and mood disorders (e.g., 82%; Brown and Barlow 1992), in studies based on *DSM-III-R* criteria. Currently, the *DSM-IV* attempts to adjust for this with a hierarchy rule stating that GAD should not be assigned if its features occur exclusively during the course of a mood disorder.

Explanations for comorbidity that do not suggest problems in the current classification systems include the possibility that features of one disorder can be risk factors for another, or that they emerge from the same diathesis. In regard to the first explanation, the results from the Brown, Campbell, et al. (2001) study indicated that the presence of PTSD was associated with a significantly elevated risk of PDA, and that, in the majority of the cases, PTSD preceded panic disorder. These findings can be interpreted to suggest that the high autonomic arousal and low perception of personal control associated with PTSD, perhaps combined with a preexisting trait such as anxiety sensitivity, may have served as precipitants to PDA. The second explanation is in accord with current theories of emotional disorders, which assert that anxiety and mood disorders share genetic, biological, and psychosocial vulnerabilities (e.g., Barlow, 2002; Clark, Watson, & Mineka, 1994).

## Hierarchical Models

The current models of emotion disorders suggest that, whereas anxiety and mood disorders emanate from the same core vulnerabilities, these vulnerabilities are manifested heterogeneously because of different environmental exposures and other biological and genetic factors (e.g., Barlow, 2002). For example, a genetically based trait of neuroticism can underlie both depression and social phobia, but whether one or both disorders become manifest may depend on environmental experience factors such as a direct experience with rejection, social humiliation, or others.

Two genetically based core dimensions of temperament have been suggested as instrumental in the etiology and course of anxiety and depressive disorders: neuroticism/negative affectivity and extraversion/positive affectivity. Research indicates that these constructs are heritable (e.g., Hettema, Prescott, & Kendler, 2004), and they may account for the onset, overlap, and maintenance of anxiety and depression (e.g., Brown, Chorpita, & Barlow, 1998).

Several conceptual models of anxiety and depression have been developed and subsequently reformulated in accordance with growing research evidence. Clark and Watson (1991) proposed a tripartite structure of anxiety and depression consisting of *negative affect* (i.e., symptoms of general distress such as worry, irritability, tension); *positive affect*, defined as a level of pleasurable engagement with the environment and characterized by features such as cheerfulness, sociability, energetic nature, and enthusiasm; and *autonomic hyperarousal*, characterized by symptoms such as rapid heart rate, shortness of breath, and trembling. This model posited that negative affect is a shared feature of anxiety and mood disorders (i.e., symptoms of tension, worry, irritability, etc., are present in both anxiety and depression). Absence of positive affect (anhedonia) was considered unique to mood disorders, whereas autonomic hyperarousal was viewed as specific to anxiety. However, this model did not account for the diversity of symptoms of anxiety disorders. Subsequent research (e.g., Brown et al., 1998) found that the higher-order dimensions of negative and

positive affect accounted for all the covariance among latent variables, corresponding to the *DSM-IV* constructs of unipolar depression, social phobia, GAD, OCD, and PDA. However, autonomic arousal was not specific to all anxiety disorders but was uniquely related to panic disorder. The same study (Brown et al., 1998) found that the absence of positive affect was related not only to depression but also to social phobia. Comorbidity and genetic study findings (e.g., Brown, Campbell, et al., 2001; Kessler, Stang, Wittchen, Stein, & Walters, 1999) also reveal a relationship between unipolar depression and social phobia that may be suggestive of a higher-order vulnerability dimension specific to these two disorders. To address these shortcomings, the tripartite model was reformulated as the hierarchical model of anxiety and depression, in which each disorder consists of both a shared and a unique component (Mineka, Watson, & Clark, 1998). The shared component corresponds to individual differences in general distress and negative affect, representing a higher-order factor common to both anxiety and mood disorders. The unique component for each disorder consists of the specific features that distinguish it from the other disorders.

Barlow (2000, 2002) has formulated a triple vulnerability model of emotional disorders that integrates genetics, personality, cognitive and neuroscience, and emotion and learning theories. The first diathesis, "generalized biological vulnerability," corresponds to the genetically based core dimensions of temperament (e.g., neuroticism). The second, "generalized psychological vulnerability," refers to the perceived sense of uncontrollability, which is manifested as one's tendency to process failures and perceived flaws as an indication of an inability to cope with unpredictable negative events. This propensity may be learned from certain early life experiences, such as overcontrolling parenting style (Chorpita & Barlow, 1998).

Together, generalized biological and psychological vulnerabilities may produce an emotional disorder. However, there is also a third set of "specific psychological vulnerabilities," which, in combination with the other two diatheses, contribute to the development of specific emotional disorders. These vulnerabilities also emerge from early learning experiences, and they refer to one's tendency to focus anxious apprehension on the perceived danger of specific events, thoughts, or objects. For example, "thought–action fusion," conceptualized as a specific psychological vulnerability for OCD, may develop when individuals learn from parents or other important caregivers to equate dangerous thoughts with dangerous actions. Similarly, "anxiety sensitivity," conceptualized as a specific psychological vulnerability for panic disorder (Taylor, 1999), may appear when individuals learn early on that unexplained somatic sensations are dangerous and could indicate illness or death.

Genetic evidence is consistent with the models of emotion disorders. For example, in a study of 1,033 blindly assessed female–female twin pairs, Kendler, Neale, Kessler, Heath, and Eaves (1992a) estimated 30% heritability for GAD (the remainder of the variance may be accounted for nonshared environmental factors). Subsequent research in all-female and mixed-set twin sample (e.g., Kendler, 1996; Kendler, Gardner, Gatz, & Pedersen, 2007; Kendler, Neale, Kessler, Heath, & Eaves, 1992b) has found that a genetic influence exists in GAD and that the genetic factors in GAD are completely shared with major depression. Although these findings may be interpreted as further indication of the overlap in anxiety and depression, empirical evidence suggests otherwise. For example, Kendler et al. (1992b) found that, although GAD and major depression share genetic factors, their environmental determinants are distinct.

In summary, evidence and predictions stemming from the current models of emotional disorders (e.g., Barlow, 2002) and genetic studies (e.g., Kendler et al., 2007) propose that although most constructs of the *DSM-IV* anxiety and mood disorders are relatively distinct (e.g., Brown, 2007), a certain degree of overlap exists between these categories. This overlap may include features such as neuroticism and behavioral inhibition, which represent genetic/biological vulnerability dimensions. Other explanations are also possible for this overlap, including erroneous splitting of a broader syndrome into categories and overlap in the diagnostic criteria. Hence, more research is needed to determine the validity of these positions.

Studies have begun to emerge that examine the relations of the *DSM-IV* disorder constructs with vulnerability dimensions. For example, Brown and colleagues (1998) examined the structural relations of unipolar depression, GAD, panic disorder/agoraphobia, OCD, and social phobia, and the dimensions of negative affect, positive affect, and autonomic arousal in a cross-sectional study. A sample of 350 patients with *DSM-IV* anxiety and mood disorders were assessed using a variety of questionnaires and

clinician ratings. A confirmatory factor analysis of the latent structural dimensions of key features of the aforementioned five *DSM-IV* disorders demonstrated the discriminant validity of *DSM-IV* for these constructs; the five-factor model (i.e., mood disorders, GAD, panic disorder/agoraphobia, OCD, social phobia) provided the best fit for the data. Interestingly, model fit decreased significantly when indicators of mood disorders and GAD were collapsed into a single factor, hence supporting the differentiation of these constructs. However, the GAD factor was most strongly correlated with the mood disorder latent factor ($r = .63$), suggesting that the features of GAD have the most overlap with the mood disorders.

As noted earlier, this study also evaluated relations among the five *DSM-IV* disorder latent factors and the latent factors of negative affect, positive affect, and autonomic arousal, finding that the higher-order dimensions of negative affect and positive affect explained almost all of the covariance among latent variables, corresponding to the *DSM-IV* disorder factors. Although all paths from negative affect to the *DSM-IV* disorder factors were statistically significant, corresponding to the predictions that negative affect is a shared feature of emotional disorders, the strongest paths from negative affect were to GAD and mood disorders (path coefficients = .74 and .67, respectively), thus supporting the arguments that GAD and depression are associated with the highest levels of negative affect.

In a more recent study, Brown (2007) expanded on previous findings, examining the temporal course and temporal structural relationships of latent dimensions of temperament (i.e., neuroticism/behavioral inhibition and behavioral activation/positive affect) with a focus on three disorder constructs—unipolar depression, GAD, and social phobia—in a sample of 606 patients with anxiety and mood disorders. Confirmatory factor analyses indicated that the latent factors of neuroticism/behavioral inhibition and behavioral activation/positive affect were distinct from GAD, social phobia, and depression. Neuroticism/behavioral inhibition and behavioral activation/positive affect accounted for most of the covariance among the *DSM-IV* disorder constructs. Neuroticism/behavioral inhibition had the strongest relationship with GAD and depression. Behavioral activation/positive affect was more strongly related to depression and social phobia than to GAD, similar to the findings of Brown et al. (1998). The findings on the temporal course of latent dimensions of

temperament and the disorder constructs are discussed elsewhere in this chapter.

## Dimensional Versus Categorical Classification

Thus far, research literature reviewed in this chapter demonstrates a considerable overlap among the anxiety and mood disorders. This is evident in studies of comorbidity (e.g., Brown, Campbell, et al., 2001), nonspecificity of treatment response (e.g., Tyrer, Seivewright, Murphy, Ferguson, Kingdon, Barczak, et al., 1988), and the remission of comorbid conditions following treatment of psychosocial disorder (e.g., Brown, Antony, & Barlow, 1995). On the other hand, there is evidence that the dimensional features of the *DSM* anxiety and mood disorders are distinct, despite some overlap (e.g., Brown, 2007). Moreover, this overlap can be accounted for by a higher-order dimension of neuroticism/negative affect. However, most of these studies relevant to the classification of anxiety and depressive disorders have a significant design problem. Specifically, the majority of these studies have been conducted at the diagnostic level (e.g., family and twin studies, Kendler et al., 2007). This approach presents notable limitations (e.g., Brown & Barlow, 2005). For example, reliability, comorbidity, family, and genetic studies conducted at the diagnostic level are restricted to the disorder definitions specified by the classification system. Additionally, data at the diagnostic level reduce information by artificially collapsing variability above and below an arbitrary threshold, such as presence or absence of a *DSM-IV* disorder. This, in turn, reduces statistical power and introduces additional measurement error.

The limitations of a categorical approach to classification have been apparent in many studies. For example, as previously mentioned, in the reliability study of Brown, Di Nardo, et al. (2001), one of the major sources of unreliability was interviewer disagreement on whether the disorder met the *DSM* threshold. This problem can manifest in two different ways. In some cases, both raters agree that the key features of the disorder are present, but they disagree on whether they cause sufficient impairment or distress to meet the *DSM-IV* threshold for a disorder. This is also apparent in disagreements involving "not otherwise specified" diagnoses, when both raters concur that clinical features of the disorder are present, but they disagree on the number and duration of symptoms that are sufficient to meet the criteria. Similarly, this problem is evident in diagnostic

disagreements involving MDD and dysthymia, as core features of depression are noted by both raters, but disagreement occurs with regard to the severity or duration of these symptoms. Finally, although dimensional ratings of the severity of depression are reliable ($r = .74$), a poor level of agreement has been found for the *DSM-IV* categorical severity specifiers ($\kappa = .30$; Brown, Di Nardo, et al., 2001).

Additionally, imposing categories on dimensional phenomena leads to loss of valuable information. For example*, DSM* does not cover clinically significant symptom presentations that do not meet criteria for formal diagnostic categories (Widiger & Samuel, 2005). This is reflected in the high rate with which NOS diagnoses are assigned (Brown, Campbell, et al., 2001). The *DSM* also does not provide a mechanism to record the severity of disorders (e.g., the severity of a comorbid mood disorder rather than merely its presence may be more relevant to the course and treatment outcome of an anxiety disorder). Information is also lost because of adherence to the hierarchical exclusions and differential diagnostic decision rules posed by the *DSM*. These rules are in place to avoid excessive comorbidity and to increase diagnostic reliability. For example, according to the *DSM-IV*, a diagnosis of GAD should not be assigned if its features occur exclusively within the course of a mood disorder. Adherence to such rules may lead to misleading findings about comorbidity of disorders. For example, in the Brown, Campbell, et al. (2001) comorbidity study, the comorbidity rate of GAD and dysthymia was only 5% when the *DSM* hierarchical rules were followed. This result contradicts the evidence pointing to substantial genotypic and phenotypic overlap of GAD and mood disorders (e.g., Brown et al., 1998; Kendler et al., 1992b). Indeed, when this diagnostic hierarchy rule was ignored, the comorbidity rate of GAD and dysthymia rose to 90%. Artifacts of *DSM-IV* differential diagnosis rules are also evident in other patterns of comorbidity, such as lower estimates of PDA co-occurrence with social and specific phobia (Brown, Campbell et al., 2001). While decreasing undue comorbidity, the *DSM* differential diagnostic rules obscure important clinical information about the nature of one's symptoms and overall level of functioning, which may have important implications for treatment planning and prognosis. Clinical information may be potentially presented more completely if dimensional systems are utilized.

Although the utility of dimensional classification has been recognized, no strong proposals have been made about how dimensional classification can be included in the *DSM*. First (2005) argues that a purely dimensional classification system may complicate clinical assessment, as well as the communication between mental health professionals. The question then becomes how dimensional elements can be incorporated into the categorical system. Brown and Barlow (2005) suggest introducing dimensional ratings of severity to the present diagnostic categories and their symptom criteria, a method similar to the one utilized in the ADIS-IV-L. This appears to be a practical alternative, as it would allow the categorical system to remain intact, and the dimensional rating can be optional for settings in which its implementation is less feasible (e.g., primary care). This approach may help address some of the problems with the present system, such as its inability to convey the severity of a disorder or clinical characteristics that may be significant, but are either subsumed by another disorder (e.g., GAD occurring exclusively within the course of a mood disorder) or do not meet the severity or the number of symptoms defined by the *DSM* (e.g., subclinical or NOS diagnoses). Because dimensional ratings would be added to the current diagnostic categories, this approach would have several advantages, including its basis on a preexisting and well-studied set of constructs, as well as its ability to retain the functional analytic and temporal aspects of a diagnosis that are difficult to be conveyed using a purely psychometric approach. Inclusion of the dimensional ratings would also provide a standardized assessment system that would allow for across-site comparability in a study of dimensional models of psychopathology. This approach may be the initial step that would help determine the reliability and feasibility of more complex dimensional systems, such as quantifying higher-order dimensions of temperament.

However, despite its usefulness, such an approach would leave some of the main problems with the categorical classification system unresolved, including poor reliability and high comorbidity. For example, the previously mentioned information variance (i.e., the difference in the patient's report of information), which is the most common reason for disagreements in reliability studies (e.g., Brown, Di Nardo et al., 2001), would remain the case with dimensional assessment as well. However, if diagnostic classification was focused at higher-order dimensions, these problems might be improved.

Indeed, it has been suggested that the classification system be driven by dimensions corresponding

to biologically and environmentally based constructs of temperament and personality (e.g., Clark, 2005). This is in line with the aforementioned theories and empirical evidence that the overlap in anxiety and mood disorders may be due to the fact that these disorders share biologic-genetic and psychosocial diatheses (e.g., Barlow, 2002). There is accumulating empirical evidence pointing to the importance of these higher-order dimensions and their implications in long-term treatment outcomes (e.g., Kasch, Rottenberg, Arnow, & Gotlib, 2002). If these broader dimensions of temperament were incorporated, the *DSM* would cease being a descriptive instrument and would become relevant to the prevention of mental disorders.

## Treatment of Anxiety and Depressive Disorders

The classification of anxiety and mood disorders has had a significant impact on treatment development. The increase in diagnostic categories across *DSM* editions has led to the development of disorder-specific interventions. The revision of agoraphobia and GAD criteria are examples of how classification

can drive treatment development. In the *DSM-III* (APA, 1980), panic disorder was regarded as different from agoraphobia, which was considered a "phobic disorder." However, a later series of studies suggested a relationship between panic disorder and agoraphobia (e.g., Thyer & Himle, 1985; Zitrin, Klein, Woerner, & Ross, 1983). The higher prevalence of agoraphobia with panic attacks in comparison to agoraphobia without panic attacks (Di Nardo et al., 1983) also supported this relationship. These findings led to the redefinition of agoraphobia as a condition secondary to panic disorder in *DSM-III-R* (APA, 1987). This change in the classification of agoraphobia and its conceptualization as apprehension about situations in which one may experience panic-like symptoms, led to a refinement of cognitive-behavioral therapy for PDA, to include exposure to anxiety-provoking situations and physical sensations (e.g., Craske & Barlow, 2007).

Similarly, GAD could not be diagnosed in *DSM-III* in the presence of any other mental disorder. However, its revision from a residual condition to a formal diagnostic category in *DSM-III-R* and *DSM-IV* led to the development of specific treatment

**Table 14.3  Additional current diagnoses among patients with principal anxiety and mood disorders**

| Additional diagnosis | DSM-IV principal diagnosis | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | PD (*n* = 36) | PDA (*n* = 324) | SOC (*n* = 186) | GAD (*n* = 120) | OCD (*n* = 77) | SPEC (*n* = 110) | MDD (*n* = 81) | Overall *a* |
| Any diagnosis | 42 | 62 | 46 | 68 | 57 | 34 | 69 | 57 |
| PD | | | 1 | 3 | 1 | 0 | 4 | 1 |
| PDA | | | 3 | 15 | 3 | 5 | 15 | 9 |
| SOC | 8 | 15 | | 36 | 26 | 9 | 41 | 22 |
| GAD | 19 | 16 | 13 | | 12 | 5 | 5 | 13 |
| OCD | 6 | 7 | 8 | 4 | | 3 | 9 | 7 |
| SPEC | 8 | 15 | 8 | 12 | 12 | 15 | 15 | 13 |
| MDD | 8 | 24 | 14 | 26 | 22 | 3 | | 20 |
| DYS | 8 | 7 | 13 | 6 | 10 | 4 | 11 | 8 |
| MDD or DYS | 11 | 17 | 20 | 29 | 40 | 4 | 0 | 18 |

PD, panic disorder; PDA, panic disorder with agoraphobia; SOC, social phobia; GAD, generalized anxiety disorder; OCD, obsessive-compulsive disorder; SPEC, specific phobia; MDD, major depressive disorder; DYS, dysthymia.
*a,* Overall frequency in which category was assigned as an additional diagnosis.
Adapted from Brown, T. A., Campbell, L. A., Lehman, C. L., Grisham, J. R., & Mancill, R. B. (2001). Current and lifetime comorbidity of the *DSM-IV* anxiety and mood disorders in a large clinical sample. *Journal of Abnormal Psychology, 11,* 592, with permission of the publisher, APA.

protocols focusing on the key feature of the disorder—excessive and uncontrollable worry (e.g., Zinbarg, Craske, & Barlow, 2006).

Indeed, disorder-specific psychological treatment protocols have now been developed for each anxiety disorder. However, the cognitive-behavioral interventions bear a lot of similarities in their components, including elements of exposure, cognitive restructuring, and between-sessions practice, and vary mostly on content to match the specific features of each disorder. Although these differentiations are helpful in addressing the nature of the disturbance, the question then becomes whether these treatments have become too specific.

## Treatment Specificity

Evidence demonstrates that anxiety and depressive disorders respond similarly to the same psychological or medical treatment. For example, a wide range of emotional disorders, including major depression, OCD, panic disorder, and GAD, have responded similarly to selective serotonin reuptake inhibitors (Hudson & Pope, 1990). Similar evidence has been obtained for benzodiazepines, tricyclic antidepressants, and monoamine oxidase inhibitors (Bandelow, Zohar, Hollander, Kasper, & Moller, 2002). In a large study, Tyrer et al. (1988) treated 210 outpatients with GAD, panic disorder, and dysthymia with diazepam, dothiepin, placebo, cognitive-behavioral therapy, or a self-help program. No difference was found in treatment response between the diagnostic groups, leading Tyrer et al. (1988) to conclude that differential diagnosis of anxiety and mood disorders was not essential for treatment planning.

Additionally, evidence suggests that psychological treatment of a specific anxiety disorder leads to a decline in other anxiety and mood disorders not addressed in treatment (e.g., Borkovec, Abel, & Newman, 1995; Brown et al., 1995). For example, Brown et al. (1995) examined the course of additional diagnoses in a sample of 126 patients in a short-term psychological treatment program for panic disorder with minimal agoraphobic avoidance. At pre-treatment, 40% of the patient had an additional diagnosis. This rate decreased to 17% at post-treatment. However, at 2-year follow-up, the rate of comorbidity increased to 30%, which was no longer significantly different from pre-treatment. These findings could be interpreted in accord with the explanation for comorbidity and theoretical models stating that disorders emerge from the same vulnerabilities. It is possible that while cognitive-behavioral therapy was effective in reducing the symptoms of panic disorder, it was not sufficient to reduce the general predispositional features such as neuroticism, which left patients vulnerable to other disorders.

However, these conclusions are speculative, because the above-mentioned studies did not measure vulnerability traits. It is possible that that the temperamental dimensions of neuroticism/negative affect and extraversion/positive affect are temporally stable and less responsive to treatment. Longitudinal studies are starting to emerge examining the temporal course of dimensions of temperament. Kasch et al. (2002) examined the temporal stability of behavioral inhibition and behavioral activation in 41 individuals with major depression over a period of 8 months; most of these individuals received treatment during the follow-up period. Lower behavioral activation at Time 1 predicted poorer clinical outcome for depression at the 8-month assessment. The self-report measures of behavioral inhibition and behavioral activation were highly stable over time, regardless of the presence of depression at the follow-up.

The aforementioned study by Brown (2007) also examined the temporal course and temporal structural relationships of dimensions of neuroticism/behavioral inhibition and behavioral activation/positive affect and *DSM-IV* constructs on unipolar depression, GAD, and social phobia, reassessing the participants at 1-year and 2-year follow-ups. Because the majority of the study participants (76%) received psychotherapy following their intake, the rate of anxiety and mood disorders decreased significantly between the intake (100%) and the 2-year follow-up (58%). Behavioral activation/positive affect evidenced a very high degree of temporal stability, consistent with its conceptualization as a trait vulnerability construct that is relatively unaffected by treatment. Neuroticism, on the other hand, evidenced the greatest amount of temporal change of the five constructs examined (Cohen's $d$ = .70), inconsistent with previous findings (e.g., Kasch et al., 2002), and it was associated with the largest treatment effect ($d$ = -.98). However, it is possible that the self-report of temperament is affected by mood state (e.g., Clark, Vittengl, Kraft, & Jarrett, 2003). Hence, the measurement of neuroticism/behavioral inhibition may consist of some combination of stable temperament variance and variability due to generalized distress, which is likely to be temporally less stable and to covary with changes in the severity of disorders. Other studies have also demonstrated that scores on measure of temperament change from pre- to

post-treatment (e.g., Clark et al., 2003). Moreover, Clark et al. (2003) implemented multivariate statistical procedures to differentiate between trait and state components of their measure of temperament. They found that changes of depression severity at post-treatment correlated with changes in the state component of the measure, but not with the trait scores.

Additionally, Brown (2007) demonstrated that neuroticism/behavioral activation operated differently than the *DSM-IV* disorder constructs. Whereas, for the disorder constructs, higher initial severity was associated with greater symptom decreases over time, the finding was opposite for neuroticism/behavioral inhibition; patients with higher initial levels of neuroticism/behavioral activation showed less change in it over time. Hence, it appeared that, unlike the *DSM-IV* disorders, the stability of neuroticism/behavioral inhibition increased as a function of initial severity.

Because dimensions of temperament have been conceptualized as risk factors for emotional disorders, studies have examined whether pre-treatment levels of these dimensions are related to treatment response and long-term course of emotional disorders. Previous studies have yielded contradictory results for depression, some showing that higher pre-treatment scores on temperament measures were associated with poorer treatment outcome (e.g., Geerts & Bouhuys, 1998; Kasch et al., 2002), whereas other studies reported no such effects (e.g., Boyce & Parker, 1985; Clark et al., 2003). Brown (2007) examined directional effects among temperament and disorder constructs over 2-year follow-up. Higher levels of neuroticism/behavioral inhibition were associated with less improvement in GAD and social phobia. Lower levels of behavioral activation/positive affect were associated with poorer outcome for the social phobia construct. However, this effect was no longer significant when neuroticism/behavioral inhibition was included in the analyses. No temporal relations were obtained for the *DSM-IV* construct of depression. The *DSM-IV* disorders did not have directional effects on dimensions of temperament. Moreover, change in neuroticism/behavioral inhibition accounted for all the temporal covariance of the *DSM-IV* disorder constructs. This suggests that either neuroticism may be affected by therapy, or a reduction in disorder severity is associated with a reduction in general distress, a feature shared by all emotional disorders. Overall, the results of this study demonstrate in a longitudinal context the role of neuroticism/behavioral inhibition as a unifying construct accounting for the covariance among the emotional disorders.

## Transdiagnostic Treatments

The emerging evidence on commonalities among the anxiety and mood disorders, including their overlapping key features and comorbidity, has led to the development of transdiagnostic approaches to the treatment of emotional disorders. It has been noted that virtually all specialized treatments for anxiety and mood disorders consist of similar components: psychoeducation, cognitive reappraisal, changing behaviors associated with the particular emotion, and exposure. Although some variations are disorder-specific, the general principles are similar. Furthermore, the earlier cited evidence on improvement of comorbid disorders after cognitive-behavioral treatment for one disorder (e.g., Brown et al., 1995) have suggested that there may be an underlying mechanism to emotional disorders that could be the focus of treatment.

Several transdiagnostic treatment approaches have been developed, based on the processes common to emotional disorders. For example, Barlow, Allen, and Choate (2004) have developed a unified protocol for treatment of anxiety and depression that suggests that maladaptive emotional regulation strategies such as suppression and avoidance are a component of all emotional disorders. This protocol begins with psychoeducation about the nature and purpose of emotions, and how they become "disordered." It then focuses on cognitive reappraisal, changing emotion-driven behaviors, and preventing emotional avoidance. As in other cognitive-behavioral treatments, exposures are an essential part of treatment. However, in the unified protocol, they are not designed to target a particular disorder; they are rather defined as "emotion exposures," the focus of treatment being emotional avoidance as opposed to the symptoms associated with a specific disorder.

Hayes and colleagues (1996) have argued that categorical classification of disorders, such as that implemented in the *DSM-IV*, does not adequately convey pathological processes underlying the disorders. They have suggested the dimension of experiential avoidance (i.e., engaging in maladaptive behaviors to avoid other psychological experiences) may be central to many forms of psychopathology. Based on this theory, Hayes, Strosahl, and Wilson (1999) developed *acceptance and commitment therapy*, which incorporates acceptance of emotional experience, mindfulness, and behavioral change that is accordance with one's values.

Several other transdiagnostic approaches have been developed, with an emphasis on enhancing treatment effectiveness and facilitating treatment dissemination. Most of them have focused on providing group cognitive-behavioral treatment to individuals with various anxiety and depressive disorders. For example, Erickson, Janeck, and Tallman (2007) reported a medium-size effect in a randomized waitlist controlled study of group cognitive-behavioral therapy (CBT) for various anxiety disorders. Erickson (2004) reported medium to large effect sizes in an uncontrolled trial of group CBT for anxiety disorders. In a randomized waitlist controlled study, Norton, Hayes, and Hope (2004) found a significant decrease in depressive symptoms following a transdiagnostic group treatment for anxiety. More recently, McEvoy and Nathan (2007), in a benchmarking study, demonstrated that effects of group transdiagnostic treatment for emotional disorders are similar to those of diagnosis-specific treatments. Overall, these studies provide support for the transdiagnostic cognitive-behavioral treatment of anxiety and depressive disorders. However, unlike Barlow's unified protocol and Hayes and colleagues' acceptance and commitment therapy, these approaches do not offer a unified theory about the processes common to emotional disorders.

Transdiagnostic approaches to treatment of anxiety and depression present several advantages over the use of disorder-specific treatments. First, they reflect the recent advances in our understanding of etiology and maintenance of emotional disorders. Some of these approaches view symptoms of the disorders as manifestations of this vulnerability and attempt to address it instead of the specific symptoms. Additionally, such approaches may facilitate treatment dissemination, but condense available interventions into a more widely applicable form. Despite these benefits, further research is needed to evaluate the efficacy of these treatments. It will also be important to investigate the effects of such treatments on the higher-order dimensions of vulnerability, such as neuroticism.

## Conclusion

This chapter focused on issues pertaining to the classification of anxiety and mood disorders and the relevance of these issues to treatment planning. The extant literature points to considerable overlap among the various anxiety and mood disorders. This is evident in studies demonstrating high rates of current and lifetime comorbidity at the diagnostic level (e.g., Brown, Campbell, et al., 2001), nonspecificity

of treatment response (e.g., Tyrer et al., 1989), and the remission of comorbid conditions following psychosocial treatment of the principal disorder (e.g., Brown et al., 1995). On the other hand, evidence suggests that the dimensional key features of the *DSM* anxiety and mood disorders display a high level of discriminant validity, despite a certain degree of overlap (e.g., Brown, 2007; Brown et al., 1998). Moreover, most of the shared variance of these emotional disorder constructs can be accounted for by a higher-order dimension of general distress/neuroticism.

The principal position outlined in the chapter was that overlap in anxiety and mood disorders may provide important clues to understanding the origins and maintenance of these syndromes and be of importance in treatment planning. This position is consistent with one potential explanation of comorbidity that high co-occurrence of disorders at the descriptive level is the result of their common etiological roots.

### Future Directions

This hypothesis awaits future research to further refine issues on the classification of emotional disorders. Several suggestions can help refine the research in this direction. First, as noted previously in the chapter, greater emphasis on dimensional measures of psychopathological phenomena and disorders will help further clarify the latent structure of these measures and the relationship between them. The increased use of latent variable approaches to data analysis will provide the advantage of adjusting for measurement error and will allow for statistical comparison of models reflecting competing theories of causality or classification. Finally, by incorporating multiple measures associated with the higher-order vulnerability dimensions (e.g., negative affect, behavioral inhibition, perceived control), researchers could examine issues such as the prediction of the emergence of specific disorders and the extent to which the defining features of emotional disorders overlap with these traits. This latter focus also would address suggestions made by researchers for increased empirical consideration of those common traits of emotional disorders that may hold strong predictive value to the prevention, etiology, course, and treatment response of emotional disorders.

It is hoped that these methodological refinements will be increasingly applied to three other important avenues of classification and pathogenesis research—genetic, longitudinal, and treatment outcome studies. Greater emphasis on dimensional

assessment of psychopathology (e.g., latent disorder constructs) in twin studies, combined with the use of latent variable approaches, could lead to important advances beyond evidence on the heritability and familial aggregation of disorders focused at the diagnostic level, where estimates of genetic liability are influenced by increased measurement error and diminished statistical power associated with collapsing dimensional variability above and below the *DSM* threshold.

There are several important potential directions for longitudinal research. Studies of at-risk and large nonclinical samples will allow investigators to identify the contribution of dimensions implicated as vulnerability factors (e.g., neuroticism) in the prediction of emotional disorders and to determine whether these higher-order traits are more explanatory than the constructs suggested to be disorder-specific (e.g., thought–action fusion for OCD). Additionally, large-scale clinical studies addressing issues such as the temporal stability and covariation of disorders and their underlying constructs, and effects of life stress on the relationship between temperament and psychopathology are crucial for increasing the understanding of the direction of the relationship among disorders and vulnerability constructs. For instance, given the evidence that the effects of vulnerability on psychopathology may be affected by stressful life events (Kendler, Kuhn, & Prescott, 2004), the Brown (2007) study may have underestimated the influence of neuroticism/behavioral inhibition and behavioral activation/positive affect on the course of the *DSM-IV* disorder constructs. Finally, large-scale clinical studies focusing on the bidirectional influence of temperament and *DSM-IV* disorders during the course of psychosocial treatment, as well as the effects of transdiagnostic treatments on the higher-order dimensions of vulnerability, will provide further evidence for determining the direction of the relationship among disorders and vulnerability constructs. These questions await longitudinal study in twin, community, at-risk, and clinical samples.

# The Nature and Treatment of Bipolar Disorder and the Bipolar Spectrum

Michael W. Otto *and* Allison J. Applebaum

**Abstract**

In this chapter, we review the nature and treatment of bipolar disorder. We first present a perspective on the disorder, based on the dominant bipolar I and II classifications, and review the current state of medication and empirically supported psychosocial interventions (e.g., cognitive-behavioral therapy, family-focused therapy, interpersonal and social rhythm therapy, and group treatment), including factors that lead to poor treatment response. Given the increased attention to how bipolar I and II may lie at one end of a continuum of patterns of mood instability, we subsequently address spectrum conceptualizations of bipolar disorder. The proposed spectrum models are presented and then considered in relation to revised prevalence rates and treatment implications.

**Key Words:** Bipolar disorder, bipolar spectrum, cognitive-behavioral therapy, family-focused therapy, interpersonal and social rhythm therapy

Bipolar disorder is a disabling, chronic, and prevalent condition. The disorder is defined by periods of mood instability and is most frequently characterized by repeated episodes of depression and at least one manic or hypomanic episode. A full manic episode is defined by a period of 1 week (unless interrupted by treatment or other factors) of feeling euphoric, irritable, or high, along with three or more of the following symptoms: exaggerated feelings of importance, racing thoughts, distractibility, little need for sleep, pressured speech, and reckless behavior (American Psychiatric Association, 2000). Hypomanic episodes are similar to manic episodes, except that they are less severe and impairing. The bipolar I subtype of bipolar disorder is defined by at least one episode of mania, whereas the bipolar II subtype refers to individuals who have had at least one hypomanic, but not full manic, episode and one or more depressive episodes.

Although there is variation in the pattern of episodes, in the most common presentation, bipolar patients typically experience several episodes of depression before the emergence of the initial manic episode (Lish et al., 1994; Suppes et al., 2001), and depressive symptoms are generally present more often than manic/hypomanic symptoms (Colom, Vieta, Daban, Pacchiarotti, & Sanchez-Moreno, 2006; Judd et al., 2003). For example, Judd et al. (2003) found that a sample of bipolar I patients felt depressed three times as many weeks compared to manic/hypomanic patients, and bipolar II patients had depressive symptoms 37 times more frequently than hypomanic symptoms. A predominance of depressive episodes was also reported by Colom et al. (2006). Of the smaller number of individuals who present initially with a manic episode, evidence suggests that this pattern may be more characteristic of men than women (Suppes et al., 2001).

Rates of relapse are high over the long term. Studies indicate that three-quarters of patients can be expected to relapse within 4–5 years, with half of these relapses occurring in the first year (Gitlin, Swendsen, Heller, & Hammen, 1995; O'Connell, Mayo, Flatlow, Cuthbertson, & O'Brien, 1991;

Tohen, Waternaux, & Tsuang, 1990). Moreover, impairment in role functioning and continued bipolar symptoms are common between episodes (Keck et al., 1998).

Attention to a potential spectrum of bipolar disorders dates back to Aristotle, over two millennia ago (Pies, 2007), but received further clarity in the writings of Kraepelin in the early 1900s. Kraeplin discussed a continuum of bipolar illness that ranged from cyclothymia to full manic-depressive patterns (see Brieger & Marneros, 1997), with the identification of cyclothymia as a milder form of, or a predisposition to, full bipolar disorder. A potential benefit of a continuum approach is the greater inclusion of diverse patterns of pathology under a single organizing principle—the cyclic mood instability that defines bipolar disorder—and, accordingly, the extension of treatment strategies based on bipolar disorder to more patients (Angst et al., 2003; Dunner, 2003; Moreno & Andrade, 2005). On the other hand, a liability of this approach is the potential overdiagnosis of varied subsyndromal characteristics that should not be integrated under the rubric of bipolar disorder nor share interventions with it. This tension between a continuum approach and concerns about overdiagnosis was present in the time of Kraepelin (Brieger & Marneros, 1997) and continues into the present, with proposals of new ways to expand the conceptualization of bipolar spectrum disorders (e.g., Akiskal, 2003).

In this chapter, the nature and treatment of bipolar disorder is considered, first from the perspective of the dominant bipolar I and II designations, with subsequent consideration of treatment implications associated with a spectrum conceptualization of bipolar disorder.

## Nature and Course of Bipolar I and II

Bipolar disorder has been estimated to affect between 1% and 3% of the population (Kessler, Chiu, Demlers, & Walters, 2005; Regier et al., 1990), although higher rates have been reported in select studies and for bipolar spectrum (e.g., including cyclothymia) disorders (see below). The average age of onset for bipolar disorder is in the mid-teens, with evidence of a worse course for individuals with an earlier age of onset (Perlis et al., 2004). Women and men are equally likely to receive a diagnosis of the disorder (Kessler et al., 1994), although sex differences have been found for the rapid cycling course (i.e., four or more mood episodes a year), with more women meeting criteria for a rapid-cycling subtype (Schneck et al., 2004).

Many factors are associated with an increased likelihood of mood episodes. Stressful life events that disrupt the daily routine and sleep–wake rhythms—such as the termination of a relationship—are linked with the precipitation of a mood episode (Bebbington et al., 1993; Healy & Williams, 1988, 1989) and are associated with delayed recovery and elevated relapse rates (Ellicott, Hammen, Gitlin, Brown, & Jameson, 1990; Johnson & Miller, 1997). Moreover, stressful family environments, characterized by high levels of expressed emotion and/or negative interactional patterns, have been linked to higher relapse rates (Miklowitz, Goldstein, Nuechterlein, Snyder, & Mintz, 1988; see also Prieb, Wildgrube, & Muller-Oerlinghausen, 1989). As noted, an early age of onset of bipolar disorder is also associated with a more chronic course, with fewer periods of recovery, more psychotic features, and greater suicidal ideation and role disruption (Perlis et al., 2004). Likewise, greater anxiety comorbidity has been linked with a lower likelihood of recovering from mood episodes and more frequent relapses (Otto et al., 2006), as well as poorer role functioning (Simon et al., 2004).

## Pharmacotherapy

For decades, pharmacotherapy has been the principal treatment option for individuals with bipolar disorder, with a primary intervention strategy of chronic treatment with one or more mood stabilizers. Mood stabilizers are ideally characterized by efficacy in ameliorating episodes of both mania and depression, as well as by preventing these episodes without increasing the risk of cycling into another mood state (Keck et al., 2004). Lithium (brand names Eskalith, Lithobid) most closely meets this definition and has been used as a mood stabilizer for 30 years in the United States. Anticonvulsants, such as divalproex (brand name Depakote), carbamazepine (brand name Tegretol), and lamotrigine (brand name Lamictal), and some atypical antipsychotic medications, such as aripiprazole (Abilify), olanzapine (Zyprexa), quetiapine (Seroquel), risperidone (Risperdal), and ziprasidone (Geodon) also provide elements of mood stabilization and, in some cases, depression treatment (Calabrese et al., 2004; Gao, Gajwani, Elhaj, & Calabrese, 2005; Thase et al., 2006; Tohen et al., 2003).

Given the prominence of the depressive pole in bipolar disorder, there is ample motivation to boost mood stabilizer efficacy by also treating with antidepressants. This treatment has been a standard strategy in the management of bipolar disorder (Keck et al.,

2004), but its utility is now being questioned. Despite the popularity of antidepressant prescriptions to treat bipolar depression, two recent studies have called into question the efficacy of this approach. In the first, Nemeroff et al. (2001) examined the combination of paroxetine or imipramine as an adjunct to ongoing lithium therapy for the treatment of acute bipolar depression; 117 outpatients with bipolar disorder who were suffering from a major depressive episode and had been treated with lithium for at least 6 weeks were enrolled. Results of 10 weeks of treatment indicated that the additional antidepressant treatment was not helpful for patients who maintained high lithium levels, but was helpful for those with low serum levels (i.e., the mean changes on depression rating scales from baseline to week 10 were statistically significant only among the low serum lithium level patients). The benefit of augmentation with paroxetine or imipramine for the treatment of bipolar depression may therefore only be realized among select patients who have low serum lithium levels or who cannot tolerate high serum lithium levels.

In perhaps the largest investigation of the efficacy of combined mood stabilizer and antidepressive treatment, Sachs et al. (2007) conducted a multicenter double-blind, randomized, placebo-controlled, parallel-group study of standard antidepressants (either bupropion or paroxetine) as adjuncts to treatment with mood stabilizers (lithium, valproate, carbamazepine, or other approved antimanic agents) at 22 centers in the United States (STEP-BD, protocol described later). Subjects had bipolar I or II disorder and were treated for up to 26 weeks to evaluate the effectiveness, safety, and tolerability of the adjunctive use of antidepressant medication. There were no significant differences in the percentage of patients meeting the criteria for a durable recovery (defined as eight consecutive weeks of euthymia) between those who received a mood stabilizer and an antidepressant and those who received a mood stabilizer and placebo. Rates of treatment-emergent mania or hypomania observed prospectively were similar in both groups. The results suggest that monotherapy provides as much benefit as treatment with mood stabilizers combined with a standard antidepressant for the treatment of bipolar depression. Together, the studies by Sachs et al. (2007) and Nemeroff et al. (2001) provide converging evidence that one of the primary pharmacologic strategies for intervening with bipolar depression—adding antidepressants to mood stabilizers—may offer little efficacy. In addition, there is a more longstanding concern

that the addition of an antidepressant will promote a manic episode (Moller & Grunze, 2000), although this risk appears to be less apparent for some of the more selectively serotonergic versus noradrenergic antidepressants (i.e., tricyclics; Gijsman, Geddes, Rendell, Nolen, & Goodwin, 2004; Leverich et al., 2006).

For managing bipolar depression, there is some encouraging evidence for the use of atypical antipsychotics. For example, there have been positive trials of the efficacy of quetiapine (Thase et al., 2006), as well as the efficacy of the combination of olanzapine-fluoxetine (Brown et al., 2006). However, the side-effect profile of these agents is concerning (as discussed later). As a pharmacologic alternative, there is only minimal evidence supporting the use of anticonvulsants (e.g., carbamazepine, valproate, lamotrigine) in the treatment of bipolar depression (e.g., Post, Uhde, Roy & Joffe, 1986; Sachs et al., 2002). For example, although data supports the use of lamotrigine as a relapse prevention strategy, in four out of five placebo-controlled trials, lamotrigine monotherapy failed to demonstrate efficacy for the treatment of bipolar depression (Calabrese et al., 2008). However, a pilot study suggests that lamotrigine, when added to another mood stabilizer, may have beneficial effects on comorbid anxiety disorders (Maina, Albert, Rosso, & Bogetto, 2008).

Treatments applied to bipolar disorder also include the use of benzodiazepines applied as a strategy to calm hypomanic symptoms, manage sleep and overactivity, and treat comorbid anxiety disorders. However, there is little evidence of the efficacy of this approach for managing the emergence or length of bipolar episodes (Moller & Nasrallah, 2003; American Psychiatric Association, 2002; Simon et al., 2004a).

It is also important to note that pharmacologic treatment of bipolar disorder is associated with significant problems of medication adherence (Johnson & McFarland, 1996; Keck et al., 1996, 1998). Some of these problems may arise due to the challenging side-effect profiles associated with the mood stabilizers. For example, a range of significant side effects—including weight gain with risk of diabetes, cognitive slowing, somnolence, and extrapyramidal symptoms—are common to at least some of the atypical antipsychotics (Allison & Casey, 2001; Gao et al., 2008a, 2008b; Newcomer, 2005), as well as for anticonvulsant and lithium treatment (Bowden et al., 2002; Goodwin & Jamison, 2007; Macritchie, Geddes, Scott, Haslam, & Goodwin, 2001). Comorbid substance use appears to further reduce

medication adherence (Manwani et al., 2007). Moreover, remaining on medications long term is a daunting prospect independent of specific side effects for some patients; regardless of the source of noncompliance, approximately half of samples of patients have discontinued their mood stabilizer medications within 2 months (e.g., Johnson & McFarland, 1996; Keck et al., 1996, 1998; Scott & Pope, 2002). Discontinuation of mood stabilizers brings with it the risk of relapse, particularly when the medication is rapidly terminated (Perlis et al., 2002). Furthermore, despite the advances in pharmacotherapy for bipolar disorder, recurrences of mood episodes appear to be the norm even with medication use (Gelenberg et al., 1989; Gitlin et al., 1995; Otto et al., 2006). For all of these reasons, consideration of alternatives to medication treatments is important.

## Psychosocial Treatments

In the last decade, psychosocial treatment strategies have emerged as a new and important force for the management of bipolar disorder (Otto & Miklowitz, 2004). Prior to this recent period of research growth, psychosocial treatment for bipolar disorder was relegated to a supportive role (Callahan & Bauer, 1999) or used as a strategy to enhance medication adherence (Cochran, 1984). Encouraged both by the limits of the efficacy of pharmacotherapy alone, and by evidence of a significant role for psychosocial stress and interpersonal issues in altering the course of bipolar disorder, new structured and focused psychosocial treatments for bipolar disorder emerged (Miklowitz et al., 2007; Otto & Miklowitz, 2004).

These new treatments were derived from very different theoretical orientations, but nonetheless show a striking degree of similarity in the strategies applied to the treatment of bipolar disorder. Specifically, recent randomized controlled trials of cognitive behavioral therapy (CBT), family-focused therapy (FFT), interpersonal and social rhythm therapy (IPSRT), and a comprehensive group treatment approach share a number of treatment elements, which include (a) psychoeducation designed to provide patients and (in the case of FFT) family members with a model of the nature and course of bipolar disorder, including risk and protective factors such as the role of sleep and lifestyle regularity, stress management, and medication adherence; (b) communication and/or problem-solving training aimed at reducing familial and external stress; and (c) a review of strategies for the early detection and intervention for mood episodes, including intensified pharmacotherapy, the activation of increased support, and more-frequent treatment sessions. These interventions may also be combined with cognitive restructuring, thought and activity monitoring, treatment contracting, and other interventions in individual, group, and family settings (Otto & Miklowitz, 2004).

### Cognitive Behavioral Therapy

Cognitive behavioral therapy is an effective psychosocial treatment for bipolar disorder. In early applications, it was directed successfully toward medication adherence in a brief session format (Cochran, 1984). Following this success, much more general applications of CBT have been adopted that focus on both relapse prevention and the treatment of bipolar depression. These broader protocols of treatment generally involve a combination of psychoeducation about bipolar disorder, cognitive restructuring, activity and lifestyle management, and active monitoring of mood states, with plans for early interventions.

For example, Perry, Tarrier, Morriss, McCarthy, and Limb (1999) emphasized the role of 12 sessions of individual CBT in the early detection and formulation of an action plan for prodromal bipolar symptoms in 69 outpatients who had a relapse during the past 12 months. This intervention was compared to treatment as usual, and the results indicated a significant difference in the length of time until manic relapse. However, the treatment was not effective in reducing depressive relapses over the 18-month study and follow-up period. Perry et al. (1999) hypothesized that the prodromal symptoms of mania are more distinct than those of depression, and therefore more easily identifiable to patients.

Lam and colleagues (2000, 2003) examined a brief program of individual CBT (12–18 sessions within the first 6 months and two booster sessions in the second 6 months of care) relative to usual care alone. Following the promising results of the pilot study (Lam et al., 2000), Lam et al. (2003) conducted a randomized controlled study of CBT in 103 bipolar patients. Patients who received CBT had significantly fewer bipolar episodes, higher social functioning, and decreased mood symptoms and fluctuation in manic symptoms during the 12-month study period than did patients in the control group. Moreover, although the participants were not experiencing an acute bipolar episode at recruitment, more than 56% had mild to moderate levels of depression at study entry, and the results indicated that CBT significantly reduced these residual symptoms of depression.

Relapse prevention was the primary focus of a study by Scott, Garland, and Moorhead (2001). The key elements of their intervention included psychoeducation, training in medication adherence, stress management, cognitive restructuring, and regulation of activities and sleep. After 6 months of treatment, patients who received CBT had significantly greater improvements in depressive symptoms and global functioning than did patients in the waitlist condition. Furthermore, patients in the CBT group showed a 60% reduction in relapse rates at the 18-month follow-up point.

Finally, Scott et al. (2006) examined the impact of 22 sessions of CBT versus treatment as usual in 253 patients with severe and recurrent bipolar disorder over 18 months. The overall results were disappointing; there were no differences between the groups for time to recurrence of an episode and symptom severity ratings. However, post-hoc analyses revealed an interaction between treatment efficacy and the number of previous episodes. Those patients with greater than 12 episodes showed no benefit from CBT, whereas a benefit was evident for those with fewer episodes. Although it is not clear whether this finding will be replicated, these results encourage the *early* application of CBT.

### Interpersonal and Social Rhythm Therapy

The theoretical basis of IPSRT comes from the instability model of bipolar disorder (Goodwin & Jameson, 1990) that identifies three potential precursors to recurrence of a bipolar episode: (1) medication noncompliance; (2) disruption in social rhythms; and (3) stressful life events. Interpersonal and social rhythm therapy addresses all three of these potential precursors (Frank et al., 1997). The treatment is derived from interpersonal therapy for depression (Klerman, Weissman, Rounsaville, & Chevron, 1984) and targets the interpersonal context within which manic and depressive symptoms arise.

Similar to traditional interpersonal therapy, IPSRT focuses on four problem areas: grief over loss (and grief over the "lost healthy self"), interpersonal conflicts, role transitions (i.e., changes in one's employment situation as a result of a mood episode), and interpersonal deficits. Unlike traditional interpersonal therapy, IPSRT includes an additional focus on the impact of stressful life events on patients' social and circadian rhythms.

Frank et al. (1997) examined the impact of individual IPSRT on relapse prevention. Their treatment included four phases that focused on the following: (1) personal history, identification of problem areas and education about bipolar disorder; (2) the identification and resolution of personal problems and typical triggers of rhythm disruption; (3) the establishment of the patient's confidence in the use of IPSRT techniques; and (4) termination, with an emphasis on signs of episodes and vulnerabilities, and a plan for the future. Patients received either IPSRT or clinical status and symptoms review treatment (CSSRT, Frank et al., 1990), which provided support and education while assessing the presence of depressive or manic symptoms and medication side effects. The results indicated that, after 1 year, patients assigned to IPSRT showed significantly greater stability of daily routines than those in CSSRT.

Frank et al. (1999) examined the effects of changing treatment modality on the onset of bipolar episodes. Participants were assigned to one of the following four conditions, each representing the intervention used during the acute and preventative phases over two years: CM (clinical management)/CM, CM/IPSRT, IPSRT/IPSRT, and IPSRT/CM. Seven out of 40 patients assigned to stable (versus altered) treatments experienced a recurrence, compared to 17 out of 42 patients assigned to altered treatment. There was no clear benefit of one treatment modality over another. However, changing treatment modality was strongly correlated with recurrence. The results indicated that stability of treatment is more important than the particular treatment modality administered, which is consistent with evidence that significant life changes can precipitate a bipolar episode (Goodwin & Jameson, 1990). In a 2-year outcome study of the same protocol (Frank et al., 2005), 175 acutely ill bipolar I patients were randomized into the four previously mentioned conditions. The results indicated that there was no difference between treatment types in time to stabilization, but patients assigned to IPSRT in the acute treatment phase survived longer without a new affective episode, regardless of the maintenance treatment to which they were assigned. The authors concluded that IPSRT—administered particularly during the acute phase—promotes a stability of social rhythms that is protective against future relapse.

### Family-focused Therapy

Family-focused therapy is grounded in the conceptualization that the symptoms of bipolar disorder are exacerbated by high levels of familial expressed emotion and life events that are disruptive to a regular daily routine. Not only are bipolar episodes often

precipitated by significant life events (i.e., those that disrupt the regularity of the daily sleep–wake cycle), but patients who return to a stressful family environment following hospitalization were more likely to relapse (Miklowitz et al., 1988). Family-focused therapy is based upon skills-oriented family interventions that have been applied effectively to delay relapses in schizophrenia (e.g., Falloon et al., 1985; Hogarty et al., 1991; Leff, Kupfers, Berkowitz, & Sturgeon, 1985; Tarrier et al., 1988). Family-focused therapy includes psychoeducation about bipolar illness; communication enhancement training, in which patients rehearse the expression of positive and negative feelings, active listening, and requesting changes in others' behaviors; and problem-solving skills training, in which patients learn to identify, define, and solve specific family problems that are related to the course of bipolar disorder (Miklowitz & Goldstein, 1997).

Miklowitz, George, Richards, Simoneau, and Suddath (2003) examined the impact of FFT and pharmacotherapy on the management of bipolar disorder. They enrolled 101 patients in FFT or less intensive crisis management (CM) and evaluated them every 3 to 6 months for 2 years. All participants were maintained on their prestudy medication regimen. The treatment involved all available family members and was administered in 21 one-hour sessions (12 weekly, 6 biweekly). Patients assigned to FFT remained remitted or partially remitted for longer intervals than did those assigned to CM, and they showed greater reduction in mood disorder symptoms and better adherence to their medication regimens.

Rea et al. (2003) conducted a randomized clinical trial of FFT versus individual treatment. Participants were 53 recently manic, bipolar patients receiving mood stabilizers who were assigned to either a 9-month manual-based FFT or an individually focused treatment. Patients were assessed every 3 months for 1 year of treatment and 1 year of follow-up. The results indicated that patients who received FFT were less likely to be rehospitalized during the study and experienced fewer mood disorder relapses. However, the impact of FFT was strongest after completion of the treatment protocol. The authors hypothesized that the skills and coping strategies gained by patients and family members may require a period of absorption and may be realized only through the active management of the illness.

Simoneau, Miklowitz, Richards, Saleem, and George (1999) examined the impact of FFT on communication between family members of those with bipolar disorder. The authors compared 9 months of FFT to crisis management with naturalistic follow-up (CMNF, which consisted of two sessions of home-based family education and ongoing crisis intervention and supportive problem solving as needed). Members of families who received FFT showed more positive nonverbal, but not less negative nonverbal, interactional behavior 1 year after treatment had been completed. Moreover, patients in FFT who became more nonverbally positive over the year showed greater improvements in mood. The results suggest the importance of positive nonverbal engagement with others as an index of mood stability.

Finally, Clarkin, Carpenter, Hull, Wilner, and Glick (1998) examined the impact of 15 sessions of marital therapy and medication management (mood stabilizers, antidepressants, and antipsychotics) for 11 months on medication adherence and mood in 19 patients who were either married or living with a significant other for more than 6 months at study entry. There was no effect of the intervention for time to recurrence or symptomatic status, but patients who received the intervention showed improvements in global functioning and increased medication adherence.

### Group Treatment

Group treatment, a potentially cost-effective alternative to individual or family therapy, has also been found to prevent recurrences in patients with bipolar I and II disorder. In addition to focused psychoeducation and skill-building interventions, the group format affords members the opportunity to learn illness management skills from other members, and provides them with an arena in which to practice problem-solving and effective communication skills. For example, in an open treatment trial, Bauer, McBride, Chase, Sachs, and Shea (1998) examined a two-phase manual-based group approach (the "Life Goals" program), which consisted of five weekly group sessions that focused first on relapse prevention, and then on problem-solving around social and occupational goals. At the end of treatment, patients showed increases in their knowledge about the disorder, and 70% reached their first self-identified behaviorally based life goal (e.g., finding a job).

In a much larger study, Colom et al. (2003) examined the impact of group psychotherapy in 120 bipolar I and II outpatients in remission. Patients were randomized to receive standard

psychiatric care with standard pharmacologic treatment, and either a structured group-based "psychoeducation" or a nondirective group therapy. Although termed psychoeducation by the authors, the treatment was a comprehensive series of 21 sessions that included interventions that demonstrated efficacy individually (i.e., a focus on the early detection of prodromal symptoms [e.g., Perry et al., 1999]; the enhancement of treatment compliance [Cochran, 1984]; and induction of lifestyle regularity [Frank et al., 1999]), and education about avoiding alcohol and street drugs and coping with the interpersonal consequences of past and future episodes. The group treatment significantly reduced the number of relapsed patients and the number of recurrences per patient, and increased the time to depressive, manic, hypomanic, and mixed recurrences. The number and length of hospitalizations per patient were also lower in patients who received group treatment.

### Bipolar Depression and Psychotherapy

Given recent evidence for the low efficacy of antidepressant treatments for bipolar depression (Nemeroff et al., 2001; Sachs et al., 2007), the potential for psychosocial treatments for this phase of the disorder emerges as a particularly important issue. In the large-scale National Institute of Mental Health (NIMH)-sponsored Systematic Treatment Enhancement Program for Bipolar Disorder (STEP-BD) protocol, this issue was examined at 15 study sites where patients were randomized to receive intensive psychosocial treatment (up to 30 sessions of CBT, IPSRT, or FFT over 9 months), or a minimal psychosocial intervention (collaborative care [CC], consisting of three sessions over 6 weeks). All four interventions included psychoeducation about bipolar disorder, relapse prevention planning, and illness management interventions. Collaborative care provided a brief version of common psychosocial strategies shown to be beneficial for bipolar disorder (Miklowitz, 2006; Miklowitz & Otto, 2006), whereas the intensive treatments were enhanced versions of CBT, IPSRT, and FFT, with additional treatment targets, including cognitive distortions and activity and skill deficits in CBT; disturbances in interpersonal relationships and social rhythms in IPSRT; and disturbances in family relationships and communication in FFT (Miklowitz et al., 2007). Results from the STEP-BD protocol supported the efficacy of all three psychotherapy approaches and indicated that these intensive psychosocial treatments

are more effective than collaborative care in enhancing recovery from bipolar depression and increasing the likelihood of remaining well (e.g., Miklowitz et al., 2007). Recovery rates were significantly greater (64.4% vs. 51.5%), and time to recovery was significantly shorter, among patients who received intensive psychotherapy plus pharmacotherapy, than among patients who received collaborative care plus pharmacotherapy. Also, it is noteworthy that the intensive psychotherapies succeeded where antidepressant medications failed. That is, the intensive treatments were associated with efficacy in largely the same cohort of patients who failed to respond to randomized antidepressant treatment (Sachs et al., 2007).

In further analyses of the same data set, Miklowitz et al. (2007) examined the impact of intensive psychosocial treatment and pharmacotherapy on role functioning. Patients who were assigned to one of the intensive psychosocial treatments had better overall functioning, relationship functioning, and life satisfaction scores over the 9-month study period, than did patients who received CC. These results indicated that the intensive psychosocial treatments were more effective than brief psychoeducation in enhancing these functional outcomes.

### Factors That Lead to Poor Treatment Response

Comorbidity with other disorders is frequent among patients with bipolar disorder. The prevalence of comorbid anxiety disorders in epidemiologic and clinical studies ranges from 7.8% to 47.2% for social anxiety disorder, 7% to 40% for post-traumatic stress disorder, 10.6% to 62.5% for panic disorder, 7% to 32% for generalized anxiety disorder, and 3.2% to 35% for obsessive-compulsive disorder (for a review, see Simon et al., 2004b). Studies of clinical populations (Brady, Castro, Lydiard, Malcolm, & Arana, 1991; Goldberg, Garno, Leon, Kocsis, & Portera, 1999) and community samples (Kessler et al., 1997; Regier et al., 1990) have revealed high rates of substance use disorder (SUD) comorbidity, with prevalence rates ranging from 21% to 45%. There is also evidence that bipolar disorder is comorbid with eating disorders (McElroy et al., 2001) and attention-deficit disorder (Nierenberg et al., 2005).

Comorbidity in general is associated with a poorer course of illness (McElroy et al., 2001). For example, comorbid anxiety and bipolar disorder has been linked with a greater likelihood of being in a mood episode, poorer role functioning and quality of life, decreased likelihood of recovery from a mood

episode, poorer response to some medications, and a greater likelihood of suicide attempts (Henry et al. 2003; Otto et al., 2006; Simon et al., 2004). Moreover, comorbid panic disorder and/or high levels of somatic anxiety have been found to be predictors of poor response to IPSRT (Feske et al., 2000). Studies have also found that comorbidity with attention-deficit hyperactivity disorder in children and adolescents with bipolar disorder is predictive of poor treatment response (Masi et al., 2004; Strober et al., 1998). Decreased medication compliance (Goldberg et al., 1999; Keck et al., 1996), hospitalization (Brady et al., 1991; Reich, Davies, & Himmelhoch, 1974), and poorer recovery (Keller et al, 1986; Tohen, Waternaux, & Tsuang, 1990) are also common among bipolar patients with comorbid substance use disorders.

Suicide is particularly associated with bipolar disorder, with lifetime prevalence rates of attempts as high as 30% in some samples (Chen & Dilsaver, 1996; Oquendo et al., 2000; Oquendo & Mann, 2001). In one study that evaluated suicidal outcomes over 20 years in a sample of 7,000 psychiatric outpatients (Brown, Beck, Steer, & Grisham, 2000), bipolar patients were found to have the highest risk for completed suicide and nearly a four-fold increase in suicide risk, as compared to the other psychiatric patients in the sample. The risk for suicide is particularly elevated in patients with comorbid bipolar and substance use disorders (Dalton, Cate-Carter, Mundo, Parikh, & Kennedy, 2003).

Comorbid personality disorders are also considered predictors of poor treatment response. Personality disorders have been associated with increased rates of psychiatric symptoms, decreased response to lithium treatment, and poorer treatment outcome, including poorer social and occupational functioning (Carpenter, Clarkin, Glick, & Wilner, 1995; Dunayevich et al., 2000; Kutcher, Maton, & Korenblum, 1990). One study (Kay, Altshuler, Ventura, & Mintz, 2002) found that male bipolar disorder patients with a comorbid personality disorder were prescribed more medications, were less likely to have been employed in the last 6 months, and more frequently had a history of a substance use disorder than did patients without Axis II pathology.

Finally, an early onset of bipolar disorder has been found to increase the risk for a severe course and poor treatment outcome (Carter, Mundo, Parikh, & Kennedy, 2003; Perlis et al., 2004). Early age of onset is also a risk factor for rapid cycling, suicidal ideation, and comorbidity with substance use disorders

(Perlis et al., 2004; Tohen, Greenfield, Weiss, Zarate, & Vagge, 1998; Tsai et al, 2001).

## Consideration of Bipolar Spectrum Disorders

Treatment-outcome research has been organized around the diagnostic categories of bipolar I and bipolar II disorder. Nonetheless, commensurate with greater attention to dimensional approaches throughout psychopathology research (Krueger, Watson, & Barlow, 2005), over the last decade increasing attention has been paid to elucidating how bipolar I and II disorder may lie at one end of a continuum of patterns of mood instability. Although this recent attention has not embraced a fully dimensional approach, it has sought to clarify additional categories of diagnoses along a continuum of severity.

A helpful starting point in this process is to first consider the lower severity disorder, cyclothymia. As compared to bipolar disorder, cyclothymic disorder is defined as a chronic (at least 2 years in duration), fluctuating mood disturbance involving numerous periods of hypomanic and depressive symptoms, which are insufficient in number, severity, pervasiveness, or duration to fulfill the criteria for a manic episode or major depressive episode, respectively (American Psychiatric Association, 2000). Cyclothymia has been largely ignored in psychopathology studies, despite calls for greater attention a decade ago (Brieger & Marneros, 1997).

An additional approach to considering the bipolar spectrum concerns diagnostic criteria and the discrimination between disorder and nondisorder. For example, according to current DSM definitions (*Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition, Text Revision,* DSM-IV-TR; American Psychiatric Association, 2000), a duration of 4 days is needed for an active state to be considered a hypomanic episode. Angst and associates (2003), however, have found that the mean duration of hypomanic episodes is 1–3 days, and therefore many hypomanic episodes miss the threshold required by the DSM and are subsequently not diagnosed (Akiskal et al., 2000). Moreover, DSM-IV-TR requires that an individual have either euphoric or irritable mood in order to be labeled hypomanic. Yet, patients rarely seek treatment as a result of these symptoms of hypomania (instead the symptoms of depression typically bring patients into treatment, Benazzi, 1999), and the diagnosis of bipolar II based upon patient report of past symptoms may be unreliable (Rice et al., 1986). Perugi and Akiskal (2002) assert

that the accurate diagnosis of bipolar II depends on the extent to which clinicians query both patients and family members about past hypomanic episodes, with a focus on overactive behavior and increased productivity.

This emphasis on overactivity is reflected in a study that sought to determine the frequency of bipolar spectrum disorder in remitted depressed outpatients. Benazzi (2003b) included subsyndromal hypomania (as defined by an episode of overactivity and at least two hypomanic symptoms) in the diagnostic criteria. In the sample of 111 patients presenting with major depressive disorder, subsyndromal hypomania was present in 39.5% of the cases, and the frequency of bipolar spectrum disorder was 76.5%. The author concluded that by focusing more on overactivity than mood change, and including subsyndromal hypomania, diagnostic criteria can better capture an essential cohort of patients in need of treatment.

Angst et al. (2003) sought to test the diagnostic criteria for DSM-IV hypomania and to validate the criteria for a definition of softer expressions of bipolar disorder by examining data from a 20-year prospective community cohort study of 4,547 young adults. Their results suggested that symptoms of overactivity should be included in the principal criteria of hypomania, whereas episode duration should not be a criterion as long as three of seven signs/symptoms are present, and that a change in functioning should remain necessary for a rigorous diagnosis. Angst and associates also note that below this threshold, "hypomanic symptoms only" associated with major or mild depression are important indicators of bipolarity. Their proposed framework is one of the broadest definitions of the bipolar spectrum, which includes the following:

- *Bipolar I.* Hospitalized mania plus major depression
- *Hard Bipolar II.* Major depressive episodes associated with a hypomanic syndrome (euphoria, irritability or overactivity), the experience of consequences from these symptoms, and three of seven signs and symptoms of DSM-IV hypomania
- *Soft Bipolar II.* Major depressive episodes associated with hypomanic symptoms only
- *Minor Bipolar Disorder (MinBP).* Dysthymia, minor depression, or recurrent brief depression associated with a hypomanic syndrome or hypomanic symptoms only
- *Pure Hypomania.* A hypomanic syndrome without any diagnosis of depression, or hypomanic symptoms only

Given this proposed revision of the diagnostic criteria for hypomania, Angst et al. (2003) report that the altered criterion led to a doubling of the proportion of bipolar II diagnoses, from 5.3% to 11%, based on their community sample.

## Rethinking Unipolar Depression

According to the conceptualization of Perugi and Akiskal (2002), the term "bipolar spectrum" refers not only to a continuum of substhreshold and threshold cases (with a duration as brief as 1 day), but includes patients who experience major depressive episodes that are superimposed on cyclothymic or hyperthymic temperamental characteristics. Perugi and Akiskal (2002) propose the enlargement of the current bipolar II disorders to include a spectrum of conditions (ranging from mood, anxiety, impulse control, and eating disorders) caused by such a cyclothymic-anxious-sensitive disposition, with mood reactivity and interpersonal sensitivity. This approach would result in the reclassification of patients originally diagnosed with unipolar depression along the bipolar spectrum.

Benazzi examined the potential role of unipolar major depression and co-occurring anger (Benazzi, 2003a) and racing thoughts (Benazzi, 2005) in defining mood episodes that may be more aptly placed on a continuum with bipolar disorder. Clinical criteria that were used to support the inclusion of major depression with anger or racing thoughts on the bipolar spectrum were age of onset, major depressive episode recurrences, atypical features of depression (e.g., overeating, oversleeping, rejection sensitivity), depressive mixed state (major depressive episode and three or more hypomanic symptoms), and bipolar family history. In each of these studies, patients with anger and racing thoughts were separately compared to depressed patients without these characteristics and patients with bipolar II disorder. Both major depression with anger and major depression with racing thoughts were significantly associated with atypical depression, as well as with early age of onset, mixed state, and bipolar family history. Although Benazzi (2003a, 2005) concludes that major depression with anger or racing thoughts may lie on a bipolar spectrum midway between major depression without anger or racing thoughts and bipolar II, it is far from clear whether these features really signify subtypes of the disorder that reflect a bipolar spectrum. Moreover, it should be noted that it is mood reactivity and rejection sensitivity that, in part, defines the atypical subtype of depression. Furthermore, the presence of anger in major depression appears to

confer little treatment relevance; these patients appear to respond like those without anger to mono-therapy with antidepressants (Benazzi, 2003a).

Akiskal and Benazzi (2005) examined the potential of atypical depression (DSM-IV-TR criteria for the atypical specifier require mood reactivity plus overeating or weight gain, oversleeping, leaden paralysis, and interpersonal rejection sensitivity [at least two], and absence of melancholic or catatonic features) as a marker for bipolar spectrum disorder. The authors compared 348 bipolar II and 254 outpatients presenting with major depressive episodes on bipolar validators, which included age of onset, high depressive recurrence, depressed mixed state, and bipolar family history (types I and II). The results indicated that patients with atypical depression had significantly higher rates of bipolar II and that atypical depression was significantly associated with all of the proposed bipolar validators, particularly family history. The authors conclude that atypical depression may be viewed as a variant of bipolar II, and that patients who present with major depressive episodes with atypical features should be considered for a bipolar II diagnosis. In considering this proposition, it is important to note that atypical depression accounts for up to one-third or more of many outpatient samples of treatment-seeking patients with major depression (McGrath et al., 2000), and the data suggest that those with atypical depression may preferentially respond to monoamine oxidase inhibitor (MAO-I) pharmacology (Quitkin et al., 1990) has done little to inform pharmacologic treatment of bipolar patients.

## Categorizing the Bipolar Spectrum

One result of research on the bipolar spectrum has been the expansion of categorical considerations that may exist along a spectrum of mood instability. Although validating studies are still pending, Akiskal and Pinto (1999) have proposed one such system that illustrates both a more detailed discrimination of potential subgroups and a much broader consideration of symptom profiles within a bipolar classification scheme:

• *Bipolar I½, depression with protracted hypomania*. This subgroup of patients is defined by the presence of protracted hypomanic periods, which cause patients and their significant others difficulty without reaching the destructive potential of a full manic episode. This category is described as one that accounts for the difficulty with demarcating the end of hypomania and beginning of mania, with bipolar I½ patients existing between these extremes.

• *Bipolar II, depression with hypomania.* By DSM-IV-TR definition, these patients have moderately to severely impairing major depressions, interspersed with hypomanic periods of at least 4 days' duration without marked impairment. Although these patients' behavior can be characterized by elated mood, confidence, and optimism, their judgment is relatively preserved compared with patients with mania. However, the course of bipolar II may involve periods of significant dysfunction, including suicide attempts. The authors note that a growing number of patients do not meet criteria for this category, as a result of their hypomanic episodes lasting less than the 4 days indicated by DSM-IV.

• *Bipolar II½, cyclothymic depressions*. This category refers to patients who have short hypomanic episodes (i.e., less than 4 days) and a recurrent pattern of periods of excitement followed by "mini-depressions," thereby fulfilling criteria for cyclothymic disorder. In a comparative analysis of the different subgroups within the bipolar spectrum using the French National EPIDEP study, Akiskal et al. (2006) found that BP II½ accounted for 33% of all major depressive episodes and emerged as the most prevalent and severe expression of the bipolar spectrum.

• *Bipolar III, antidepressant-associated hypomania*. This category refers to patients who develop manic or hypomanic episodes during treatment with an antidepressant. They also often have early-onset dysthymia, with a family history of bipolar I disorder.

• *Bipolar III½, bipolarity masked—and unmasked—by stimulant abuse*. This category refers to patients whose periods of excitement are so closely linked with substance or alcohol use and abuse that it is difficult to determine if these periods would have occurred in the absence of such use and abuse. The inclusion of this category may bring the potential benefit of mood stabilization to patients who otherwise might be classified as having substance-induced or substance withdrawal–induced mood disorders. Camacho and Akiskal (2005) note that premorbid cyclothymic and hyperthymic traits, a family history of bipolarity, and the presence of subthreshold bipolar signs during periods of protracted sobriety are common to these patients. On the other hand, clinicians are often met with

the challenge of differentiating mood swings that are related to mania or hypomania from those that result from substance use and/or withdrawal, and it is possible that patients with substance use disorders may be misdiagnosed and unnecessarily treated for mood disorders (e.g., Hirschfeld, 2001; Hirschfeld & Vornik, 2004).

• *Bipolar IV, hyperthymic depression.* This category includes patients who experience clinical depression later in life that is superimposed on a lifelong hyperthymic temperament (which the authors describe as part of the long-term functioning of the individual, as opposed to being episode bound). Patients are typically men in their fifties whose life-long drive, ambition, high energy, confidence, and extroverted interpersonal skills helped them to advance and achieve success in their life. Unlike the brief hypomanias of bipolar II and III, the hyperthymic traits of these individuals are maintained for much of their lives at a more or less stable level.

## Bipolar Disorder and Borderline Personality Disorder

Another diagnostic group that is under examination for reclassification as a bipolar spectrum disorder is borderline personality disorder. Comorbidity between the disorders is high (e.g., Deltito et al., 2001; Paris, Gunderson, & Weinberg, 2007), and there is evidence that diagnostic reliability is aided by examination of interepisode functioning. For example, George, Miklowitz, Richards, Simoneau, and Taylor (2003) examined patients with bipolar disorder who were currently in remission and found that personality disorders were diagnosed in 28.8% of the sample. Cluster B (dramatic, emotionally erratic) and cluster C (fearful, avoidant) personality disorders were more common than cluster A (odd, eccentric). Moreover, patients with personality disorders had more severe residual mood symptoms, even during remission, than did patients without personality disorders. However, this diagnostic clarity is muddled for patients with chronic but less clear-cut mood symptoms (i.e., bipolar II versus bipolar I disorder), including rapid mood changes that are hard to differentiate from the situation-specific mood disturbances that may be part of a personality disorder. Akiskal and Pinto (1999) hypothesize that the overlap between bipolar and borderline personality disorder is situated within their conceptualization of bipolar II½. In particular, they propose that, because cyclothymic patients may present with depressive moodiness characterized by brief depressive mood swings instead of exhibiting clear cut hypomanic features, they are easily misdiagnosed with borderline personality disorder.

## Revised Prevalence

As might be expected, the expansion of symptoms considered to be within a bipolar spectrum leads to much higher prevalence rates than the 1%–2% associated with traditional bipolar I and II. When the full spectrum of bipolar disorders is considered, current data suggest lifetime prevalence rates as high as 11% for community samples (Angst et al., 2003; Judd & Akiskal, 2003; Lewinsohn, Klein, & Seeley, 1995; Moreno & Andrade, 2005; Szadoczky, Papp, Vitrai, Rihmer, & Furedi, 1998). For example, in a reanalysis of the Epidemiological Catchment Area (ECA) study, Judd and Akiskal (2003) raised the lifetime prevalence from 1.3% to 6.4% by including a subgroup of patients with subsyndromal symptoms of mania.

One effect of using a spectrum approach is not just the identification of undiagnosed cases, but a reclassification of unipolar depression as bipolar spectrum. Indeed, as part of the French National EPIDEP study, Akiskal et al. (2006) examined the prevalence of the soft bipolar spectrum disorders and concluded that, when considered together, the spectrum (bipolar I, II, II½, III, III½, IV) accounted for 65% of all major depressive episode cases, making unipolar depression less prevalent than bipolar disorder, as redefined by these researchers.

## Bipolar Spectrum Disorders: Treatment Implications

Research on bipolar spectrum classification systems has made it clear that limited hypomanic symptoms are common among individuals with unipolar depression, and are also common among individuals with comorbid Axis I and II disorders (e.g., borderline personality disorder or substance dependence). However, it is not known whether the presence of these symptoms has meaning relative to treatment. Regarding pharmacotherapy, it is not clear whether the use of mood-stabilizing agents—lithium, anticonvulsants, and atypical antipsychotics—would be appropriate for the subsyndromal characteristics that define many bipolar II spectrum patients. Moreover, for patients with unipolar depression, consideration of mood-stabilizing agents is already part of treatment algorithms (e.g., Crossley & Bauer, 2007), and it is unclear whether the bipolar spectrum

designation would lead to earlier discrimination of those likely to fail antidepressants alone and need such augmentation. In fact, preliminary evidence suggests that subsyndromal bipolar features do not discriminate depressed patients who are more likely to respond to this treatment approach (Hantouche, Akiskal, Lancrenon, & Chatenêt-Duchêne, 2005). Furthermore, the utility of spectrum classification schemes will be competing in the future with alternative (e.g., genetic) strategies for identifying responsive and nonresponsive cohorts for given medications (e.g., Stamm et al., 2008).

Similar considerations are apt for the overlap between bipolar spectrum and borderline personality disorder. Application of mood stabilizers is already under way for some of the core symptoms of borderline personality disorder, with some evidence for their efficacy for affect instability and aggressive behavior (Diaz-Marsa et al., 2008; Herpertz et al., 2007), although, as might be expected, they had little effect on unstable relationships, impulsivity, suicidality, and global functioning. Similar outcomes were evident for antidepressant treatment (Nosè, Cipriani, Biancosino, Grassi, & Barbui, 2006).

Regarding the impact of bipolar spectrum disorders relative to treatment with psychotherapy, research suggests that patients with subsyndromal characteristics are well represented in psychosocial practice. Specifically, Stirman, DeRubeis, Crits-Christoph, and Rothman (2005) examined patients in clinical practice relative to entry criteria for clinical trials. They found that a prominent reason for the divergence between patients studied in clinical trials of psychotherapy and patients seen in clinic practice was the over-representation of patients who did not meet duration or severity criteria for disorders in clinical trials. Also, it is important to note that some of the strategies for CBT for bipolar disorder (e.g., Otto et al., 2009) represent an extension of those traditionally applied to unipolar depression (see also Totterdell & Kellett, 2008; Zaretsky, Segal, & Gemar, 1999). Furthermore, given the role assigned to atypical depression in identifying patients who are relegated to a bipolar spectrum diagnosis (Akiskal & Benazzi, 2005), it is promising that the efficacy of CBT for this subtype of depressed patients compares well to the preferred pharmacotherapy for this cohort (Jarrett et al., 1999). Nonetheless, recent successful treatment trials for bipolar disorder (Miklowitz et al., 2007) may help expand the interventions used by clinicians for these subsyndromal patients.

## Conclusion

At this time, treatment outcome research for bipolar disorder has been marked by two important findings. First, recent studies have provided cautions about the efficacy of antidepressant medications for bipolar depression. This finding may bring about a new search for efficacious alternatives, while helping physicians refrain from prescribing antidepressant agents that may add little efficacy while increasing the side-effect and treatment-adherence burden. Second, in the face of this limiting evidence for one popular pharmacologic strategy for bipolar depression, recent studies have shown that psychosocial treatments can have a significant and meaningful impact on bipolar depression and the course of bipolar disorder. These data help end the longstanding assumption that effective treatment of bipolar disorder lies exclusively in the realm of somatic interventions. It is now clear that psychosocial treatments, and the individuals who offer them, have a crucial role in providing patients greater control over their disorder.

### Future Directions

Confidence in the efficacy of focused psychosocial treatments for bipolar disorder is only now growing among experts in the field (Keck et al., 2004), and hence dissemination of these successful strategies to more clinicians is a central issue for psychosocial strategies for bipolar disorder. Further validation and expansion of psychosocial treatment for bipolar disorder is an area of expected growth for treatment research and intervention over the next decade. Likewise, future studies are likely to attend to the treatment of bipolar spectrum patients, with particular attention to whether consideration of a broader cohort of patients under the "bipolar" rubric truly aids treatment conceptualization and outcome for these individuals in need. Important questions to be addressed by future studies include the following:

• Is the reclassification of unipolar depressives as part of the bipolar spectrum useful for understanding the course and prognosis of mood disorders?

• Will the psychosocial treatment of bipolar depression emerge as a standard strategy for a disorder once assumed to require biological intervention?

• Will the bipolar spectrum approach lead to better treatment by expanding traditional

interventions for bipolar disorder to more individuals?

• What treatments will replace the tendency to use antidepressant medications for bipolar depression?

• Will psychosocial treatment for bipolar disorder be expanded to the treatment of comorbid conditions (e.g., anxiety and substance use disorders) in individuals with bipolar disorder?

• What is the true relationship between borderline personality disorder and bipolar II disorder?

# Obsessive-Compulsive and Related Disorders

Jonathan S. Abramowitz *and* Ryan J. Jacoby

**Abstract**

This chapter presents a comprehensive overview of the nature, psychological conceptualization, assessment, and treatment of obsessive-compulsive disorder (OCD) and putatively related conditions. First, we describe the symptoms of OCD and the proposal that numerous other problems overlap with this condition. We critically review this proposal, and conclude that the number of overlapping conditions is somewhat smaller than some authors have suggested. From there, we turn to a review of the empirically supported psychological models of OCD and these related conditions. A discussion of the assessment and treatment of these disorders then follows.

**Key Words:** Obsessive-compulsive disorder, OCD, obsessive-compulsive related disorders, OCRDs, diagnosis, treatment, exposure and response prevention, ERP, cognitive-behavioral therapy, CBT, anxiety disorders

Obsessive-compulsive disorder (OCD) has captured the attention of clinicians for over a century. Despite its somewhat low prevalence rate relative to other anxiety disorders, the presentation of OCD is usually severe and often crippling with symptoms that frequently prevent normal functioning at school or work, within social relationships, and in basic life activities (e.g., eating, personal hygiene). Further, the relatively complex psychopathology of OCD initially made the development and implementation of effective treatments difficult. Sufferers appear to struggle against unwanted thoughts and urges that are consciously recognized as senseless on the one hand and yet are perceived as signs of danger on the other. The wide array and intricate associations between thoughts and behaviors can bewilder even the most experienced and astute of clinicians.

Fortunately, since the 1970s, research on OCD has increased exponentially, leading to a better understanding of the course of this condition, its symptom heterogeneity, its boundaries with and relationships to other syndromes, and the development of increasingly refined theoretical models. Perhaps most important, research has led to advances in assessment and treatment to the point that OCD is now considered one of the most treatable psychological disorders.

This chapter begins with an overview of the nature and course of OCD. It has been proposed that numerous other psychological and neurological conditions with seemingly overlapping symptoms comprise a spectrum of *obsessive-compulsive and related disorders* (OCRDs). This proposal is reflected in the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition (DSM-5; American Psychiatric Association, 2013), although it is not uniformly supported by those in the field (Mattaix-Cols et al., 2007). We will critically examine the basis for this OCRD approach and, based on empirical evidence, define it somewhat differently than DSM-5 has. We will then turn to a critical discussion of the various conceptual models proposed to explain the symptoms of OCD and

related problems. Finally, we discuss the assessment of these conditions, describe empirically supported treatment methods, and discuss the research supporting their effectiveness.

## Definition of OCD

In the DSM-5 (American Psychiatric Association, 2013) OCD is described as characterized by two main symptoms: *obsessions, compulsions*, or both. Obsessions are persistent intrusive thoughts, ideas, images, impulses, or doubts that an individual experiences as unwanted, unacceptable, or senseless. The intrusions also evoke subjective distress (e.g., anxiety, fear, doubt) and are not simply everyday worries about work, relationships, or finances. Although highly specific to the individual, obsessions often concern themes such as (a) germs, contamination, and illness (e.g., "I'll get AIDS if I use a public restroom"); (b) responsibility for harm, disasters, mistakes, or bad luck ("what if I left the stove on and there's a fire" or "what if I hit someone with my car without realizing it"); (c) sex and morality (e.g., "senseless doubts about one's sexual orientation"); (d) violence (e.g., "what if I shake my baby"); (e) religion (e.g., "what if I've offended God"); and (f) symmetry, order, and exactness (e.g., "it's just not right unless I take an even number of steps"). Most individuals with OCD evidence multiple types of obsessions. Table 16.1 presents some examples of common obsessions.

To control their anxiety, individuals with OCD attempt to avoid situations, thoughts, and other stimuli that trigger obsessions (e.g., using the iron or stove in the case of obsessions about causing a fire). If such situations cannot be avoided, the individual may engage in compulsive rituals. Compulsive rituals are defined as behavioral or mental acts which are formulated according to a set of idiosyncratic personal "rules." Rituals are generally deliberate, yet clearly senseless or excessive in relation to the obsession they are designed to neutralize (e.g., scrubbing one's hands for 30 minutes after using the restroom, testing smoke detectors 10 times before leaving the house). As with obsessions, rituals are unique to the individual. Common *overt* rituals include excessive decontamination (e.g., cleaning, washing), counting, repeating routine actions (e.g., turning the light switch off and on several times, getting dressed five times), checking (e.g., door locks, lights), and repeatedly asking questions to seek reassurance. Some examples of *covert* or *mental* rituals include internally repeating special "safe" numbers or phrases (e.g., "God is great") to neutralize obsessional thoughts, and trying to mentally review one's actions to reassure oneself that one didn't cheat on one's partner without realizing. Table 16.2 presents examples of common rituals.

Typically there is a fair amount of variance between individuals with regard to insight into the senselessness of their obsessions and rituals. Some patients easily acknowledge the irrationality of their obsessive thoughts and compulsive rituals, while others are firmly convinced that they are entirely rational. An individual's degree of insight

**Table 16.1 Examples of common obsessions**

| Category | Example |
| --- | --- |
| Contamination | Fear of germs from urine or feces<br>What if the money I handled had germs? |
| Responsibility for harm | If I don't warn people that the floor is slippery, it will be my fault if they get hurt<br>What if I hit someone with my car without realizing it? |
| Sex and morality | Unwanted images of incestuous relationships<br>Unwanted impulses to stare at someone's crotch |
| Violence | Impulse to stab a loved one<br>Thoughts of verbally abusing an innocent or undeserving person<br>Images of death or dismemberment |
| Religion | What if I offended God by mistake?<br>Images of Jesus with an erection on the cross |
| Symmetry and order | The sense that odd numbers are "not right"<br>The thought that everything has to be arranged "just right" |

**Table 16.2  Examples of common compulsive rituals**

| Category | Case example |
| --- | --- |
| Decontamination | Hand washing for 15 minutes at a time after taking off one's shoes<br>Wiping down all mail and groceries brought into the house for fear of germs from the grocery store clerks |
| Checking | Driving back to recheck that no accidents were caused at the intersection<br>Checking locks, appliances, electrical outlets, and windows |
| Repeating routine activities | Turning the light switch off and on 18 times |
| Ordering/arranging | Saying the word "left" whenever one hears the word "right"<br>Rearranging the books on the bookshelf until they are "just right" |
| Mental rituals | Canceling a "bad" thought by thinking of a "good" thought<br>Repeating a prayer until it is said "just right" |

may change over time and can vary between his or her obsessions. For example, an individual may recognize that his obsessive thoughts about physically abusing his children are senseless and yet he may have poor insight into the irrationality of his religious obsessions. The DSM-5 criteria for OCD include the specifiers "Good or fair insight," "Poor insight," and "Absent insight" to denote the degree to which the person views his or her OCD symptoms as logical.

It is critical to note that obsessions and compulsions are *functionally related*, meaning that the compulsive ritual is indeed a response to the obsessional distress—and serves as an attempt to reduce this distress. Unfortunately, this is not reflected in the DSM-5's definition of OCD as including obsessions *or* compulsions. Indeed, from a functional perspective, one does not exist without the other. For example, an obsession with accidently leaving a door unlocked to intruders would *increase* subjective distress and a subsequent compulsive ritual such as checking door locks a prescribed number of times would *reduce* the distress caused by the obsession. Indeed, research indicates that certain obsessions and rituals tend to co-occur in the following patterns: (a) obsessions about responsibility for harm and mistakes are associated with checking rituals; (b) symmetry obsessions occur along with ordering and counting rituals; (c) contamination obsessions co-occur with washing and cleaning rituals; (d) religious, sexual, and violent obsessions often trigger mental rituals and reassurance seeking; and (e) hoarding-related obsessions (e.g., "what if I discard something very important by mistake) trigger saving compulsions (e.g., Abramowitz et al., 2010; McKay et al., 2004).

The latter group, hoarding, deserves special mention. Although hoarding has traditionally been considered a form of OCD, experts have more recently recognized important differences between hoarding and other OCD symptom subgroups (e.g., Abramowitz, Wheaton, & Storch, 2008; Frost & Steketee, 2008; Mataix-Cols et al., 2005; McKay et al., 2004; Pertusa et al., 2010; Rachman, Elliott, Shafran, & Radomsky, 2009; Wheaton, Abramowitz, Fabricant, Berman, & Franklin, 2011). For example, hoarding appears to be more strongly related with other sorts of psychopathology (e.g., personality disorders) than with OCD symptoms (e.g., Frost & Steketee, 2008). Hoarding is also associated with an earlier age of onset, a distinct neural activity pattern, and genetic susceptibility loci relative to OCD symptoms (e.g., Wheaton et al., 2008). Finally, hoarding shows a weaker response to pharmacological and psychological treatments with demonstrated efficacy for OCD (Abramowitz et al., 2003; Mataix-Cols et al., 1999). These differences are compelling enough that hoarding is now a separate diagnostic entity in DSM-5 (i.e., hoarding disorder).

## Obsessive-compulsive Related Disorders: The "OCD Spectrum"

Through DSM-IV-TR, OCD was classified as an anxiety disorder and grouped with other conditions (e.g., phobias, panic, generalized anxiety disorder) whose main features include fear, anxious apprehension, and the behavioral manifestations of these psychological states (e.g., avoidance, safety-seeking behaviors). Yet since the 1990s, some authors have asserted that OCD is incorrectly regarded as an anxiety disorder and instead belongs among a group of

*obsessive-compulsive related disorders* (OCRDs; also referred to as the "OCD spectrum"; e.g., Hollander, 1995). Initially, this group of conditions was quite broad, incorporating conditions located on a putative continuum of compulsivity and impulsivity (Hollander et al., 2005). Table 16.3 lists the OCRDs as proposed by Hollander et al. (2005), which fall into three main categories: impulse control disorders, disorders focused on appearance and bodily sensations, and neurological disorders that feature repetitive behaviors. Although the OCRD idea was initially conceived on the basis of apparent overlaps in overt symptom presentation among these disorders (e.g., repetitive thinking and repetitive behavior), proponents of this approach assert that the various disorders also overlap in terms of their neurobiology, patterns of comorbidity, familial patterns, and effective treatments (e.g., Hollander et al., 2007). As a result, in DSM-5 OCD has been removed from the anxiety disorders and now exists as the flagship diagnosis in its own category of obsessive-compulsive related disorders along with hoarding disorder, body dysmorphic disorder, hair-pulling disorder (formerly trichotillomania), and skin-picking disorder.

On both empirical and practical grounds, scientists and practitioners alike with expertise in OCD widely question (a) the removal of OCD from the anxiety disorders, (b) creation of the new OCRD diagnostic category, and (c) decisions regarding which conditions have been included as OCRDs (e.g., Mataix-Cols et al., 2007). The next section of this chapter discusses specific problems with the

OCRD approach as outlined earlier and put into practice in DSM-5.

## A Critical Review of the OCRD Approach

### FOCUS ON REPETITIVE BEHAVIOR

Proponents of the OCRD approach argue that a broad range of disorders characterized by repetitive thinking or behavior patterns are related to OCD. A problem with this argument, however, is that in most of the OCRDs, the repetitive symptoms are not functionally related in the same way that obsessions and compulsions are related in OCD. Repetitive impulsive behavior that characterizes impulse control disorders (e.g., repetitive or "compulsive" hair pulling), for example, does not serve the purpose of reducing obsessional fear. Rather it is in some way rewarding and is positively reinforced (although it might also sometimes serve to distract one from general boredom or distress). Research indicates that individuals with repetitive hair pulling and other impulse control disorders (e.g., compulsive stealing, pathological gambling) generally feel contentment, satisfaction, or even excitement when performing their impulsive behavior (Grant & Potenza, 2004). Also, the lack of evidence of a relationship between impulsivity and compulsivity (e.g., Bienvenu et al., 2000; Summerfeldt et al., 2004) is a compelling mark against a broadly defined OCRD diagnostic category that includes any impulse control problems such as hair pulling. Finally, neurological disorders such as autism spectrum disorders and Tourette's syndrome sometimes

**Table 16.3  Proposed obsessive-compulsive related disorders**

| Impulse control disorders | Appearance/bodily sensations | Neurological disorders characterized by repetitive behaviors |
|---|---|---|
| Intermittent explosive disorder | Body dysmorphic disorder | Autism |
| Pyromania | Hypochondriasis | Asperger's syndrome |
| Kleptomania | Depersonalization disorder | Tourette's syndrome |
| Pathological gambling | Anorexia nervosa | Sydenham's chorea |
| Trichotillomania (pathological hair pulling) | Bulimia nervosa | |
| Paraphilias and nonparaphilic compulsive sexual behavior | | |
| Impulsive and aggressive personality disorders such as borderline, narcissistic, and antisocial personality disorders | | |

involve repetitive behaviors (e.g., body rocking, hand flapping, physical and motor tics), but these are more akin to pointless muscle movements rather than anxiety-reducing behaviors.

There are, however, two disorders for which there might be a legitimate argument for considering as OCRDs on the basis of overlaps in behavioral features: body dysmorphic disorder (BDD, which is among the OCRDs in DSM-5) and hypochondriasis (which is now called illness anxiety disorder and classified among the somatoform disorders in DSM-5). In these two conditions, the individual experiences anxiety-provoking thoughts (i.e., of poor appearance in BDD; of serious undetected illnesses in hypochondriasis) and performs avoidance behavior or repetitive, excessive, and sometimes rule-driven behaviors to alleviate this anxiety (i.e., checking, camouflaging, or reassurance seeking in BDD; checking one's body for signs of illness and seeking reassurance from doctors in hypochondriasis; e.g., Abramowitz & Moore, 2007). Because of their bodily focus, however, both BDD and hypochondriasis were previously grouped among the somatoform disorders (DSM-IV); however, the intrusion, distress, ritual, relief cycle seen in these disorders is strikingly similar, if not identical, to that seen in OCD. Further similarities will be discussed later in this chapter, yet it is puzzling that hypochondriasis is neither an OCRD nor an anxiety disorder in DSM-5.

## NEUROBIOLOGY

Some studies have reported differences in neurobiological variables (e.g., brain structure and function) between individuals with and without OCD (e.g., Whiteside, Port, & Abramowitz, 2004); and some analogous findings have been reported in comparisons between healthy individuals and those with putative OCRDs (e.g., Chamberlain et al., 2008). Proponents of the OCRD model (e.g., Hollander et al., 2005) have interpreted such findings as confirming that some common "abnormality," "imbalance," or "defect" is responsible for *causing* OCD or OCRDs. However, neurobiological studies are generally cross-sectional and correlational, thereby only describing associations and *differences* between people with and without the disorder in question. Such studies are not designed to allow for causal or etiological inferences to be drawn. Whereas it is possible that alterations in brain functioning are the cause of OCD, it is just as plausible that experiencing the symptoms of OCD (and related mood and behavioral changes) brings about changes in the brain relative to healthy individuals. Finally, both OCD and the brain alterations could be linked to one or more third variables not included in the study (e.g., the effects of general stress, medication use). Thus, the origin and meaning of the observed neurobiological differences remain unclear.

The results of neurobiological research on OCD have also been highly inconsistent. Therefore, this body of research fails to provide convincing evidence of common neurological deficits or dysfunctions in OCD and OCRDs. In a meta-analysis of 13 neuroimaging (e.g., magnetic resonance imaging [MRI] of the brain) investigations of OCD patients, for example, Whiteside, Port, and Abramowitz (2004) found that most results could not be replicated across studies. In addition, few studies have addressed the neurobiology of the other OCRDs; and those studies in existence largely report results that are inconsistent with the findings for OCD (e.g., O'Sullivan et al., 1997; Stein et al., 1997 in trichotillomania). Thus, it is "premature to bring neurobiology into the formal classification of mental disorders" (Hyman, 2007, p. 731).

## PATTERNS OF COMORBIDITY

Although proponents of the OCRD approach have argued that OCD and its related conditions often co-occur with one another, several large studies do not support this notion. For example, Bienvenu et al. (2000) reported the following rates of OCRDs among 80 individuals with OCD: anorexia nervosa, 9%; bulimia, 4%; trichotillomania, 4%; kleptomania, 3%; pathologic gambling, 0%; and pyromania, 0%. Similarly, hoarding appears to be more strongly related to other sorts of psychopathology (e.g., personality disorders) than with OCD symptoms (e.g., Frost & Steketee, 2008). In contrast, hypochondriasis (16%) and BDD (15%) were more likely to be comorbid with OCD, supporting the position that these two disorders might be part of an obsessive-compulsive spectrum (Bienvenu et al., 2000). Other studies have reported largely similar results (e.g., Jaisoorya, Reddy, & Smith, 2003). These findings indicate that other than BDD and hypochondriasis, the proposed OCRDs are quite *uncommon* among individuals with OCD. In contrast, OCD is more often comorbid with other *anxiety disorders* (e.g., Jiasoorya et al., 2003). For example, 13% of OCD patients also met criteria for generalized anxiety disorder, 20.8% met criteria for panic disorder, 16.7% for agoraphobia, 36% for social phobia, 30.7% for specific phobias, and 54.1% for recurrent major depression (Nestadt

et al., 2001). Thus, the research is actually more in line with the view that OCD is more closely related to other anxiety disorders than it is to OCRDs (on the order of 5- to 10-fold closer).

Another problem with basing diagnostic categories on comorbidity patterns is that comorbidity merely signifies *some* association among disorders—but not necessarily a diagnostically meaningful one. Indeed, comorbidity is common in most major mental disorders, and there are numerous explanations for this phenomenon that do not require co-occurring conditions to be related to one another. As an example, alcohol dependence, depression, and PTSD are all more highly comorbid than what would be expected by chance. While there might be several reasons for the co-occurrence of these disorders, few would suggest they are all part of the same diagnostic category. Thus, comorbidity patterns are of limited value in understanding the uniqueness of OCD and its links to OCRDs.

FAMILY PATTERNS

Proponents of the OCRD approach have asserted that if OCRDs occur frequently in relatives of people with OCD, then such problems are related and share a common genetic underpinning. The available research, however, does not support this contention. For example, Bienvenu et al. (2000) found that the lifetime prevalence of trichotillomania in first-degree relatives of adults with OCD was only 1%. Moreover, studies consistently indicate that rates of anxiety disorders among first-degree relatives of people with OCD are far higher than the rates of OCRDs among relatives of OCD sufferers (e.g., Bienvenu et al., 2000; Nestadt et al., 2001). Therefore, the assertion that familial pattern represents a valid basis for grouping together the OCRDs again actually more strongly supports the notion that OCD should be grouped with the anxiety disorders. In other words, the available data are more consistent with the notion of shared genetic vulnerability among OCD and the anxiety disorders, as opposed to genetic links between OCD and the putative OCRDs.

TREATMENT RESPONSE

Proponents of the OCRD model also argue that OCD and related conditions respond to the same psychological and pharmacological treatments. As we discuss later, research has established the effectiveness of cognitive-behavioral therapy (CBT) using exposure and response prevention (ERP) techniques, and pharmacotherapy using serotonin reuptake inhibitor (SRI) medications (e.g., clomipramine and selective serotonin reuptake inhibitors [SSRIs; e.g., Prozac]) for the treatment of OCD (e.g., Abramowitz, 1997). However, among the OCRDs, response to ERP and to SRIs is highly variable; and in some cases, these are *not* the recommended treatments. For example, several studies of trichotillomania have shown no beneficial effect of SRIs relative to placebo (Christenson et al., 1991; Ninan et al., 2000; Streichenwein & Thronby, 1995; van Minnen et al., 2005). Psychological treatment for trichotillomania (and other impulse habit or control problems such as skin picking, nail biting, pathological gambling, and kleptomania) involves techniques such as habit reversal (substitution of an alternative behavior that is incompatible with the impulsive behavior) and stimulus control (avoiding high-risk situations and modifying physical aspects of an individual's environment to reduce sensory input that leads to the impulsive behavior) that are not used or recommended for OCD (e.g., van Minnen et al., 2003; Grant, Donahue, & Odlaug, 2011). Hoarding symptoms also show a weaker response to pharmacological and psychological treatments with demonstrated efficacy for OCD (Abramowitz, Franklin, Schwartz, & Furr, 2003; Mataix-Cols et al., 1999, 2002; Saxena & Maidment, 2004; Steketee & Frost, 2003), further suggesting these two problems involve separate psychological mechanisms and demand distinct cognitive-behavioral treatments. Instead, hoarding responds optimally to psychological treatments involving cognitive interventions focused on modifying dysfunctional beliefs about the meaning of possessions and emotional attachment to them (e.g., Frost & Steketee, 2008), which are not advantageous for those with OCD. Techniques such as motivational interviewing; development of attention, organization, decision-making, and problem solving skills; and the tolerating of strong emotions (including, but not limited to anxiety) are also emphasized in CBT treatments for hoarding (Steketee & Frost, 2007), none of which are components of ERP for OCD.

Thus, overall, there are insufficient data to support any linkage among OCD and these putative OCRDs as a function of treatment response. We will return to a discussion of the treatment of OCD, BDD, and hypochondriasis later in this chapter.

## Conclusions: BDD and Hypochondriasis as Possible OCRDs

As mentioned previously, while most of the conditions placed within the OCRDs category (either

broadly defined [e.g., Table 16.3] or as they appear in the DSM-5), appear not to be related with OCD, BDD appears to be an exception; similarly, hypochondriasis, which is not labeled as an OCRD in DSM-5, appears to belong in this category if such a classification exists in nature. In both of these conditions, we find anxiety-reducing behavior (e.g., checking in mirrors in BDD; checking with doctors for reassurance in hypochondriasis), which is phenomenologically linked to intrusive thoughts and (obsession-like) fears (e.g., regarding appearance in BDD; regarding one's medical health in hypochondriasis) that some disastrous consequence will occur in the future, requiring the use of avoidance or rituals to avert such outcomes and bring about a sense of safety or certainty. Moreover, BDD and hypochondriasis respond preferentially to many of the same CBT (and pharmacological) interventions used for the treatment of OCD. Based on the sum of this evidence, it would be most appropriate to include BDD and hypochondriasis in a category with OCD (most fittingly, the anxiety disorders). Therefore, the reminder of this chapter focuses on a more narrowly defined set of OCRDs than is present in the DSM-5 classification: that is, OCD, BDD, and hypochondriasis.

## Conceptual Models of OCD
### Models Based on Conditioning and Learning Theory

Until the 1980s, clinical researchers relied on conditioning models based on learning theory to understand OCD and other anxiety-based disorders. The best articulated of these models was Mowrer's (1960) two-factor model of fear, which proposed that obsessional fears were acquired by classical conditioning and maintained by operant conditioning. To illustrate, an obsessional fear of the number "666" could arise from an incident in which the person had an aversive experience (the unconditioned stimulus; which could include the experience of anxiety or fear itself) in the presence of this number (the conditioned stimulus), leading to a classically conditioned fear. The obsessional fear was then said to be maintained by negative reinforcement; that is, the anxiety-reducing effects of avoiding or escaping from distress (e.g., by avoidance of the number 666) or by engaging in compulsive rituals such as mentally "replacing" the number with a "safe" number or repeating a behavior until the number is out of one's consciousness.

ERP, which remains the most effective treatment for OCD, developed largely as a result of conditioning models such as Mowrer's (1960). ERP involves gradual confrontation with stimuli that, while realistically safe, provoke obsessional fear (i.e., exposure; e.g., touching a stair rail, thinking about or viewing the number "666"), while resisting compulsive urges to perform rituals to reduce anxiety (i.e., response prevention; e.g., refraining from washing, resisting mental rituals).

Despite the effectiveness of ERP and other treatments developed from the conditioning paradigm, these types of models have some limitations. First, most people with OCD do not report the kinds of conditioning experiences these models credit with obsession formation. Second, behavioral models have difficulty explaining the emergence, persistence, and content of repugnant sexual, religious, and violent obsessions (e.g., Why do some people with OCD experience obsessional images of Jesus masturbating on the cross?). Third, this model fails to explain why the focus of obsessions and the nature of compulsions sometimes shift over time (e.g., the patient who previously had obsessions about Jesus now has obsessions about molesting his infant). These and other limitations led researchers to consider the role cognitive processes play in the development and persistence of OCD.

### General Cognitive Deficit Models

Research in the area of cognitive deficits has primarily taken two directions. The first main area of research focuses on dysfunctions or deficits in cognitive processing, which may have neurobiological or neuropsychological origins. The idea that individuals with OCD suffer from cognitive processing deficits is intuitively appealing. For example, it seems plausible that individuals with checking rituals have a memory problem and can't remember whether they have locked the door. Alternately, individuals could have a deficit in their ability to accurately recall whether they actually turned off the oven or merely imagined doing so (i.e., a *reality monitoring* deficit). Research findings, however, provide weak and inconsistent support for these types of memory problems in OCD (Abramovitch, Abramowitz, & Mittleman, 2013). In fact, the most consistent finding has been that individuals with OCD have less *confidence* in their own memory than do individuals without OCD (e.g., Foa, Amir, Gershuny, Molnar, & Kozak, 1997; McNally & Kohlbeck, 1993; Woods et al., 2002).

Research has also examined whether the intrusive, repetitious, and seemingly uncontrollable quality of obsessional thoughts is the result of cognitive

inhibition deficits. Research in this domain posits that individuals with OCD are relatively less able than nondisordered individuals to forget or dismiss thoughts about extraneous mental stimuli. For example, when individuals with OCD are given tests of recall and recognition, they have more difficulty forgetting negative material and material related to their particular OCD concerns relative to positive and neutral material, whereas healthy control subjects do not show this bias (e.g., Tolin, Hamlin, & Foa, 2002; Wilhelm, McNally, Baer, & Florin, 1996).

Poor cognitive inhibition might explain the high frequency of obsessional thoughts, yet the idea that OCD arises from general cognitive deficits does not add to our understanding of or our ability to treat the disorder. It seems likely that apparent memory and processing deficits are better accounted for by *cognitive biases* in which obsessional anxiety leads to preferential processing of threat-relevant stimuli. For example, individuals who possess a biased perception that they are responsible for negative events or outcomes may have reduced confidence in their memory and the potential for their memory problems to lead to misfortune. Consequently, the individual may engage in compulsive checking. Therefore, checking compulsions may function as a way of reducing doubts that have arisen because of mistaken beliefs about one's memory and ability to manage uncertainty and pathological overestimates of responsibility for harm. These types of mistaken beliefs are the focus of the cognitive specificity hypothesis of OCD.

## Cognitive Specificity Models

The cognitive specificity approach to OCD proposes that OCD (and related) disorders arise from particular types of dysfunctional cognitions (i.e., beliefs and interpretations). Such models are based on Beck's (1976) cognitive specificity hypothesis, which posits that each type of psychopathology is associated with a distinct type or pattern of dysfunctional beliefs. Depression, for example, is said to arise from overly negative beliefs about oneself, the world, and the future (e.g., "I'm a loser"). Panic disorder is thought to be associated with catastrophic misinterpretations of the physical sensations that accompany normal anxiety (fight/flight) response (e.g., "When my heart races, I think I'm having a heart attack"). With respect to OCD, particular dysfunctional beliefs have been theoretically linked to particular types of symptoms. For example, beliefs about inflated personal responsibility have been

conceptually linked to obsessions about harm and mistakes, and checking compulsions (Salkovskis, 1985). Further, beliefs about the overimportance of one's intrusive thoughts (e.g., "Bad thoughts mean I'm a bad person") have been linked to violent, sexual, and religious obsessions (e.g., Abramowitz et al., in press; Frost & Steketee, 2002).

Given the heterogeneity of OCD symptoms, it is not surprising that a number of similar cognitive approaches have expanded on Beck's (1976) more general initial model. Among the best articulated of these is Salkovskis's (1985, 1989) cognitive approach. This model begins with the well-established research finding that most people experience unwanted intrusive thoughts (i.e., thoughts, images, and impulses that intrude into consciousness; e.g., Rachman & de Silva, 1978). These "nonclinical" obsessions tend to be less frequent, less distressing, and shorter in duration than the "clinical" obsessions of individuals with OCD (Rachman & de Silva, 1978; Salkovskis & Harrison, 1984). Clinical and nonclinical obsessions, however, have similar themes such as violence, contamination, sex, and doubts (Rachman & de Silva, 1978). Thus, a comprehensive model of OCD must explain why almost everyone experiences intrusive thoughts, yet only a minority of people experience frequent, distressing, and persistent clinical obsessions.

Salkovskis argues that intrusive thoughts reflect the person's current concerns and are triggered by internal or external cues that remind the person of his or her concerns. For example, intrusive thoughts about accidentally hitting pedestrians with an automobile may be triggered by driving past people walking on the side of the road. Salkovskis asserted that nonclinical intrusive thoughts only escalate into obsessions when they are evaluated or *appraised* as posing a threat for which the individual is personally responsible. To illustrate, consider the intrusive image of shaking a baby. Although upsetting, most people experiencing such an intrusion would not regard it as personally meaningful or as having harm-related implications (i.e., it would be considered "mental noise"). Such an intrusion might develop into a clinical obsession, however, if the person appraises it as indicating that he or she has the responsibility for causing or preventing the accompanying disastrous consequences. For example, if the person made an appraisal such as the following: "Thinking about hurting my baby means that I'm a dangerous and bad parent who must take extra care to ensure that I don't lose control," such appraisals would evoke distress and motivate the

person to try to suppress or remove the unwanted intrusion (e.g., by replacing it with a "good" thought), and to attempt to prevent the content of the intrusion from actually occurring (e.g., by avoiding the baby). Thus, compulsive rituals are cast in this model as efforts to remove intrusions and to prevent any perceived harmful consequences.

Why then do some people, but not others, interpret and appraise their intrusive thoughts in terms of harm and responsibility? Beck (1976) proposed that our life experiences shape the basic assumptions we hold about ourselves and the world, including beliefs about personal responsibility and about the significance of unwanted thoughts (e.g., beliefs that all our thoughts are significant). Such beliefs may be acquired from a strict moral or religious upbringing, or from other experiences that teach the person extreme or rigid codes of conduct and responsibility (Salkovskis, Shafran, Rachman, & Freeston, 1999).

But if obsessions are unrealistic, senseless thoughts, why doesn't the person with OCD recognize this and move on? Why, instead, does the person engage in useless and time-consuming rituals? Salkovskis proposed that rituals develop and persist as coping strategies for obsessional thoughts for two reasons. First, compulsive rituals are reinforced by the immediate (albeit temporary) reduction in obsessional distress that they often produce (i.e., negative reinforcement, as in the conditioning model). Second, they maintain obsessions by preventing the person from learning that his or her beliefs and appraisals are unrealistic. That is, when a person ritualizes, he or she fails to learn that obsessional thoughts and situations aren't dangerous and instead he or she continues to think that without the ritual a disaster would have occurred. Other authors (e.g., Rachman, 2003) have similarly proposed that compulsive rituals additionally increase the frequency and repetitiveness of obsessions by serving as reminders of intrusions (i.e., retrieval cues), and thereby triggering their reoccurrence. For example, compulsive reassurance seeking can remind the person of his or her obsessional doubts. Therefore, attempts to distract one's self from obsessional thoughts can paradoxically *increase* the frequency of these thoughts and images. Rituals can also strengthen one's perceived responsibility. For example, when the feared consequences of thinking a violent thought do not occur after performing a mental ritual, it strengthens the belief that the person is indeed solely responsible for removing the potential threat and must continue to prevent it from happening in the future.

In summary, the cognitive model of OCD proposes that obsessions and compulsions develop when a person habitually interprets normal intrusive thoughts as posing a threat for which he or she is personally responsible. This leads to distress and attempts to remove the intrusion to alleviate discomfort and prevent the feared consequences. But this response paradoxically increases the frequency of intrusions. Thus, the intrusions become persistent and distressing, and they escalate into clinical obsessions. Compulsive rituals maintain the obsessions and prevent the person from evaluating the accuracy of his or her interpretations. Avoidance is analogous to compulsive rituals in that avoidance functions as a strategy for reducing anxiety. Avoidance and rituals differ in that avoidance is a passive anxiety reduction strategy and ritual use is an active strategy.

Salkovskis's model emphasizes the role of responsibility appraisals of intrusive thoughts. Other authors, however, have developed additional cognitive models by expanding on the types of dysfunctional beliefs and appraisals that contribute to OCD. Although these cognitive models differ in some ways, they are more similar than they are different. Most of the differences between these models relate to the emphasis that they give to certain types of dysfunctional beliefs. Rachman (1998), for example, focuses on beliefs concerning the significance of intrusive thoughts (e.g., "If I think an immoral thought, it means I'm an immoral person"). Thus, for Rachman, obsessions arise when the person misinterprets the intrusive thought as implying that he or she is bad, mad, or dangerous. *Thought-action fusion* (TAF) is an important concept in this model (Shafran, Thordarson, & Rachman, 1996). Thought-action fusion is defined as beliefs that one's unwanted thoughts will inevitably be translated into actions (i.e., likelihood TAF; e.g., "I might cause my father to have a car accident just by thinking about it"), or beliefs that thoughts are the moral equivalent of actions (i.e., moral TAF; e.g., "Thinking about cursing at someone is just as bad as actually doing it").

The most comprehensive contemporary cognitive model of OCD was developed collaboratively by members of the Obsessive Compulsive Cognitions Working Group (OCCWG; Frost & Steketee, 2002)—an international assembly of over 40 investigators with interests in cognitive aspects of OCD. Table 16.4 lists the various domains of dysfunctional beliefs identified by the OCCWG. The OCCWG model accounts for the heterogeneity

of OCD symptoms by proposing that particular beliefs (or patterns of beliefs) are important for specific types of OCD symptoms.

## IMPLICATIONS OF COGNITIVE SPECIFICITY MODELS

The cognitive-behavioral approach provides a logical and consistent account of OCD symptoms that assumes intact learning (conditioning) processes and normally functioning (albeit biased and maladaptive) cognitive processes. It is parsimonious in that there is no appeal to "chemical imbalances" or disease states to explain OCD symptoms. Further, the hypothesized maladaptive beliefs and appraisals are viewed as "errors" rather than "disease processes." Additionally, the use of avoidance and compulsive behaviors to reduce perceived threat could be considered adaptive if harm were indeed likely. However, OCD patients' obsessive fears and rituals cease to be adaptive because they are out of proportion to the actual threat of the situation. Therefore, such avoidance and rituals are not only irrational but are highly problematic since they perpetuate a vicious cycle of intrusion → misappraisal → anxiety, and so on.

The model also suggests that successful treatment for OCD symptoms must accomplish two things: (a) the correction of maladaptive beliefs and appraisals and (b) the termination of avoidance and compulsive rituals that prevent the self-correction of maladaptive beliefs and consequent extinction of anxiety. In short, the task of cognitive therapy is to foster an evaluation of obsessional stimuli (including the experience of fear itself) as nonthreatening and therefore not demanding of further action.

Patients must come to understand their problem not in terms of the risk of feared consequences, but in terms of how they are thinking and behaving in response to stimuli that objectively pose a low risk of harm.

To illustrate, consider a patient who has recurrent doubts that she's spilled her medication on the floor and will be responsible for a child later finding these pills and poisoning himself with it. She keeps her pill bottles tightly wrapped in several plastic bags and counts the pills compulsively to reassure herself that she hasn't dropped any. This individual overestimates the likelihood of danger and holds the belief that she is solely responsible for causing (and preventing) the disaster she obsesses about. To challenge this belief, the patient and therapist can create a more realistic belief (e.g., "My bottle wrapping and counting have no influence on the feared disaster") and then devise a behavioral experiment to test the new belief. A behavioral experiment in this situation might involve deliberately opening her pill bottle in a candy store and then evaluating the consequences. Cognitive restructuring methods derived from Beck's cognitive therapy (e.g., Beck & Emery, 1985) are also used to challenge OCD-related beliefs and appraisals.

## EMPIRICAL STATUS

The cognitive specificity approach to OCD is supported by data from three lines of evidence: self-report questionnaire research, laboratory experiments, and naturalistic longitudinal studies. Results from questionnaire studies consistently indicate that people with OCD are more likely than those without to overestimate the probability

**Table 16.4  Domains of dysfunctional beliefs associated with OCD**

| Belief domain | Description |
| --- | --- |
| Excessive responsibility | Belief that one has the special power to cause and/or the duty to prevent, negative outcomes |
| Overimportance of thoughts | Belief that the mere presence of a thought indicates that the thought is significant. For example, the belief that the thought has ethical or moral ramifications, or that thinking the thought increases the probability of the corresponding behavior or event |
| Need to control thoughts | Belief that complete control over one's thoughts is both necessary and possible |
| Overestimation of threat | Belief that negative events are especially likely and would be especially awful |
| Perfectionism | Belief that mistakes and imperfection are intolerable |
| Intolerance for uncertainty | Belief that it is necessary and possible to be completely certain that negative outcomes will not occur |

of harm and interpret intrusive thoughts as meaningful, threatening, or in terms of responsibility for harm (e.g., Abramowitz et al., in press; Abramowitz, Whiteside, Lynam, & Kalsy, 2003; Freeston et al., 1993; OCCWG, 2003; Salkovskis et al., 2000; Shafran et al., 1996). Although such studies clearly suggest a relationship between OCD and cognitive variables, these correlational data do not address whether cognitive biases play a causal role in OCD onset. Thus, it cannot be ruled out that dysfunctional beliefs result *from* the presence of OCD symptoms. Results from experimentally controlled studies must be examined for evidence of causal directionality.

Several laboratory experiments have addressed the effects of interpretations of intrusive thoughts on OCD symptoms (Ladouceur et al., 1995; Lopatka & Rachman, 1995; Rassin, Merckelbach, Muris, & Spaan, 1999). In one particularly clever study, Rassin et al. (1999) connected 45 psychologically naïve participants to electrical equipment that, participants were told, would monitor their thoughts for 15 minutes. To induce dysfunctional appraisals, participants who had been randomly assigned to the experimental condition were told that thinking the word "apple" would automatically result in a mild electric shock to another person (a confederate of the experimenter) whom they had met earlier. Participants were also informed that by pressing a certain button immediately after having an "apple" thought, they could prevent the shock— this was intended to simulate a compulsive ritual. At the same time a group of subjects in the control group were told only that the electrical equipment would monitor their thoughts. Results indicated that during the 15-minute monitoring period, the experimental group reported more intrusive "apple" thoughts, more guilt, greater subjective discomfort, and more intense resistance to thoughts about apples compared to the control group. Moreover, there was a strong association between the number of reported "apple" thoughts and the number of button presses. These data suggest that intrusive thoughts and compulsive behaviors can indeed be evoked by experimentally manipulating participants' beliefs about the significance and harmfulness of intrusive thoughts.

While the results of this experiment suggest that beliefs can cause OCD symptoms in a *laboratory* setting, it cannot speak to the development of OCD in naturalistic settings. Thus, longitudinal studies in which individuals are assessed for cognitive variables and then followed up after some critical event are apt to be particularly informative.

Because pregnancy and the postpartum period represent periods of increased vulnerability to OCD onset, this life event provides an opportune time to examine hypotheses about potential cognitive determinants of OCD; in particular, will the presence of OCD-related cognitive distortions be related to postpartum OCD symptoms? To examine this question, we (Abramowitz, Khandher, Nelson, Deacon, & Rygwall, 2006; Abramowitz, Nelson, Rygwall, & Khandher, 2007) administered measures of OCD-related dysfunctional beliefs to two samples of first-time expecting parents (mothers and fathers-to-be) during the third trimester of pregnancy. Between 2 and 3 months after childbirth, these new parents were again contacted and assessed for the presence and intensity of unwanted intrusive thoughts about their newborn. Not surprisingly, 75% of these new parents reported unwanted infant-related thoughts ("nonclinical obsessions"; e.g., an image of dropping the child down the stairs or off the balcony). Moreover, after controlling for baseline levels of obsessive-compulsive symptoms and trait anxiety, the prechildbirth strength of OCD-related dysfunctional beliefs was a significant predictor of obsessive-compulsive symptom intensity in the postpartum period. These data support the cognitive-behavioral model and suggest that the tendency to overestimate the chances of harm and significance of intrusive thoughts is a risk factor for the development of more severe obsessive-compulsive symptoms.

Despite the fact that dysfunctional beliefs (as posited by cognitive models) do appear to cause obsessive-compulsive symptoms in both laboratory and natural settings, existing cognitive models of OCD may yet remain incomplete. For example, in the sample of new parents, dysfunctional beliefs only accounted for a small proportion of obsessive-compulsive symptom variance. Thus, other factors must also be involved in determining the onset of obsessive-compulsive problems. Additionally, a small group of individuals with OCD do not show the types of dysfunctional beliefs thought to be tied to OCD onset (Taylor et al., 2005). Finally, cognitive therapy techniques, which are derived from cognitive models, do not appear to be more effective than more purely behavioral therapy techniques that do not directly focus on and challenge cognitive biases (e.g., Abramowitz, Franklin, & Foa, 2002). Generally, cognitive specificity models probably hold some validity yet require modification (rather than abandonment, as in the general cognitive deficit models). Specifically,

future models should define additional etiologically relevant variables, and "boundaries" should be more clearly identified (i.e., defining the types of OCD symptoms they can and cannot account for).

## Conceptual Models of OCRDs

As discussed previously, BDD and hypochondriasis are the conditions that appear most closely related to OCD from a conceptual and empirical standpoint. The next sections provide an overview of the contemporary conceptual models of psychopathology in these conditions.

### *Body Dysmorphic Disorder*

Classified as an OCRD in DSM-5, and previously considered a somatoform disorder, BDD involves imagined or exaggerated concerns about physical defects such as obsessions about the shape or size of facial features. These appearance preoccupations are similar to obsessions in OCD in that both trigger anxiety or distress. Moreover, in individuals with BDD the avoidance and excessive behaviors designed to conceal, correct, check, or seek reassurance about the imagined defects, similar to compulsive rituals in OCD, serve the purpose of anxiety and distress reduction. For instance, some individuals with BDD check their appearance for prolonged periods of time in mirrors, windows, and so forth. Others go so far as to avoid all reflective surfaces. Additional compulsive behaviors can include comparing oneself to others, skin picking, measuring the "flawed" body parts, and seeking a cure (e.g., dental, dermatological, cosmetic, etc.) for the perceived defect (Perugi & Frare, 2005).

#### CONCEPTUAL MODEL

The most well-thought-out conceptual model of BDD is the cognitive model proposed by Veale (2004). This model proposes that episodes of heightened concern with body image in BDD are often precipitated by "external representations" of the individual's appearance—such as seeing one's reflection—which trigger a defective mental image. Through selective attention to appearance-related details, the individual experiences heightened awareness of specific characteristics within the image. This in turn offers faulty information on how the individual appears to others from an observer perspective. This imagery is then associated with greater self-focused attention, to the extent that in more severe cases of BDD all of the individual's attention may be focused on the distorted image and the poor self-evaluation.

In addition to his or her distorted self-appraisals and maladaptive degree of self-focused attention, the individual with BDD also typically holds dysfunctional beliefs and assumptions about the importance of physical appearance. The individual may endorse beliefs such as "If I'm unattractive, then life isn't worth living." Core beliefs regarding feelings of inadequacy, worthlessness, abnormality, and rejection are also activated. The individual then compares his or her "defective" features with the lofty ideal, which leads to feelings of self-disgust, social anxiety, and the fear of embarrassment or rejection, depression, and anger at oneself. These emotional responses trigger urges to perform defensive behaviors such as avoidance or active escape and concealment of the imagined defect, to prevent feared outcomes and to reduce distress. Although these safety behaviors may temporarily alleviate distress, they tend to generally maintain the self-consciousness, preoccupation with the imagined defect, and negative self-appraisal.

#### EMPIRICAL SUPPORT

Generally, empirical findings support Veale's model (see Buhlmann & Wilhelm, 2004, for a review). First, evidence from the Rey Osterrieth Complex Figure Test (Deckersbach et al., 2000) and functional magnetic resonance imaging (fMRI) scans of patients processing faces of high and low spatial frequency (Feusner, Townsend, Bystritsky, & Bookheimer, 2007) support the hypothesis that people with BDD deploy selective attention toward minute details and features, rather than on global figures. This may explain why individuals with BDD focus on specific appearance-related details while ignoring more global features. Similarly, Buhlmann, McNally, Wilhelm, and Florin (2002) found that BDD patients selectively attend to emotional BDD-related stimuli (both positive and negative) in the emotional Stroop test; thus, they are concerned about both beauty and their own perceived ugliness. Interestingly, studies of cognitive inhibition suggest that although persons with BDD experience distressing, intrusive thoughts about their appearance, they generally do not try to suppress them because they are perceived as valid (Wilhelm, Buhlmann, & McNally, 2003).

Second, studies have demonstrated that patients with BDD have significantly poorer insight than patients with OCD despite similar levels of symptom severity between groups (Eisen, Phillips, Coles, & Rasmussen, 2004). Clinical observations suggest that most OCD patients have some awareness

that others consider their beliefs unusual, and that their intrusive thoughts and compulsive rituals are caused by OCD. In contrast, many patients with BDD believe that others agree that they are ugly or deformed and that their appearance-related beliefs are not caused by a mental illness but are, in fact, reality.

Third, there also appear to be a number of interpretive biases present in BDD that overlap with social phobia. For example, individuals with BDD tend to interpret ambiguous social situations as threatening, have difficulty recognizing others' emotional expression, and tend to be biased toward interpreting others' facial expression as negative in valence (Grocholewski, Heinrichs, & Lingnau, 2007). Relative to people without BDD, those with this condition also tend to rate attractive facial photographs of others as more attractive. Thus, in general, those with BDD may be highly sensitive to beauty and aesthetics.

## Hypochondriasis (Also Known as Illness Anxiety Disorder)

Although long believed to represent a form of personality pathology, depression, or attention-seeking behavior, contemporary models of hypochondriasis cast this problem as a form of excessive anxiety focused on health and illness within the broader spectrum of anxiety disorders. There is an intuitive appeal to such a classification given that hypochondriasis is characterized by a preoccupation with fears of having, or the idea that one has, a serious disease, based on a misinterpretation of bodily sensations (American Psychiatric Association, 2013). These preoccupations also persist despite appropriate medical evaluation and reassurance from physicians. As with BDD, the psychopathology of, and efficacious treatments for, hypochondriasis are very similar to OCD. In fact, hypochondriasis can reasonably be viewed as a variant of OCD (even though it is placed in the somatoform disorders and renamed as illness anxiety disorder [IAD] in DSM-5) in which the individual is exclusively obsessed with health and disease.

### CONCEPTUAL MODEL

Recently several etiological theories for health-related anxiety have been proposed (Abramowitz & Braddock, 2008; Taylor & Asmundson, 2004). The first theory, the biopsychosocial approach, is a general theory that describes physiological, cognitive, and behavioral processes. The biopsychosocial approach specifically posits that excessive illness anxiety arises from and is maintained by dysfunctional beliefs about sickness and health, including beliefs that lead people to misinterpret the significance of and overestimate the dangerousness of normal bodily sensations and perturbations. Bodily sensations are common occurrences in healthy people (Pennebaker, 1982) and may occur for a variety of reasons, such as benign strains, minor diseases, or autonomic arousal arising from stress. People with excessive illness anxiety, however, interpret bodily changes and sensations as threatening and fear some health-related catastrophic consequence (Warwick & Salkovskis, 1990). For example, simple constipation may be misinterpreted as evidence of colon cancer and impending death, or a headache may be taken as evidence of a malignant brain tumor. Other types of beliefs held by people with excessive illness anxiety include the idea that they are healthy *only when they do not have any bodily sensations*, that doctors and medical tests cannot be trusted, and that worrying about their health will keep them safe (Taylor & Asmundson, 2004). Retrospective studies suggest that these beliefs arise from learning experiences, particularly childhood experiences, about health and disease (Taylor & Asmundson, 2004).

Dysfunctional beliefs are thought to persist in people with excessive illness anxiety for many reasons. For example, as with compulsive rituals in OCD, behaviors performed with the aim of alleviating health worries also serve to perpetuate elevated levels of health anxiety by providing cues which then prompt more worries, and by preventing the individual from learning that these worries are unfounded. Common maladaptive coping behaviors include persistent reassurance seeking (from physicians or family members), other forms of repetitive checking (e.g., bodily checking, searching the Internet for health information), and avoidance of behaviors that elicit bodily sensations (e.g., physical exertion). These behaviors persist because they are reinforced by reduced anxiety in the short term. In the long term, however, they are not only ineffective in producing lasting reductions in anxiety, but they actually serve to perpetuate pathological illness anxiety (Lucock, White, Peake, & Morley, 1998). For example, checking the Internet might increase a person's preoccupation with disease and expose him or her to frightening information about the symptoms and risks of other health conditions. Additionally, rituals may have other negative consequences. For instance, reassurance seeking may reduce the individual's sense of independence (e.g., by repeatedly turning to others for help) and make

him or her feel reliant on others for regulating his or her anxiety. Also, seeking additional interventions and tests to treat these perceived illnesses can produce iatrogenic effects, such as side effects of medications, pain from unnecessary invasive procedures, and so on (see Abramowitz & Braddock, 2006, and Taylor & Asmundson, 2004 for a discussion).

Consistent with the biopsychosocial model, research suggests that people with excessive illness anxiety more frequently tend to misinterpret their bodily sensations as indicative of disease than do nonanxious individuals (Haenen, Schmidt, Schoenmakers, & van den Hout, 1998). These anxious individuals are also more likely to overestimate the probability of contracting a disease and the seriousness of diseases (Ditto, Jemmott, & Darley, 1988; Easterling & Leventhal, 1989). The fact that environmental factors account for most of the individual differences in scores of illness anxiety (63%–90% of the variance) whereas genetic factors played a significant but less important role (10%–37% of the variance) is also consistent with the biopsychosocial model (Taylor, Thordarson, Jang, & Asmundson, 2006). Other psychosocial factors implicated in the etiology of clinical levels of illness anxiety include early learning experiences (e.g., childhood history of disease, reinforcement or receiving special attention when sick), which contribute to dysfunctional beliefs about the dangerousness of bodily changes and that one's body is weak (e.g., Robbins & Kirmayer, 1996; Whitehead et al., 1994). Research has also demonstrated that performing checking, reassurance-seeking, and other ritualistic behaviors results in a short-term decrease in health worries (Abramowitz & Moore, 2007).

## Assessment

Proper assessment of OCD and related disorders is guided by the conceptual models of psychopathology discussed in the previous sections. Due to the consistent empirical support for behaviorally and cognitively oriented models, such models are used as a framework for determining which parameters are appropriate to assess. Methodologies for a comprehensive assessment of OCD, BDD, and IAD are discussed in this section.

### Clinical Interviews

Three psychometrically validated structured clinical interviews exist for the diagnosis of OCD and related disorders. The *Anxiety Disorders Interview Schedule for DSM-IV* (ADIS-IV; DiNardo, Brown, & Barlow, 1994) is a clinician-administered, semistructured interview developed to allow for differential diagnosis among the anxiety disorders based on DSM-*IV* criteria. The ADIS-IV begins with demographic questions and items related to general functioning and life stress. Sections for assessing each anxiety, mood disorder, and two somatoform disorders (hypochondriasis and somatization disorder) appear next. The OCD and hypochondriasis sections each begin with a screening question; a positive answer to this question triggers more detailed questions about specific symptoms based on DSM criteria.

Studies demonstrate that the ADIS has very good interrater reliability, with the main sources of unreliability stemming from the occasional assignment of a subclinical OCD diagnosis (rather than a different anxiety disorder) (e.g., Brown et al., 2001). Although no studies have directly examined the validity of the ADIS-IV OCD section, many studies do show that OCD samples diagnosed with the ADIS-IV have higher scores on other measures of OCD severity than do non-OCD samples. This provides some indirect evidence of validity. The semistructured format of the ADIS is also advantageous because it allows the clinician to collect more detailed information. The dimensional rating of symptom severity provided in this interview is also frequently useful. One drawback of the ADIS is that administration of the full instrument can be time consuming. However, it should be noted that the OCD module itself is relatively short.

The *Structured Clinical Interview for DSM-IV Axis I Disorders* (SCID; First, Spitzer, Gibbon, & Williams, 2002) is a second clinician-administered interview. However, the SCID, unlike the ADIS, was developed for the purpose of diagnosing a range of DSM-IV Axis I disorders. Consequently, the SCID contains modules designed for the assessment of OCD, BDD, and hypochondriasis/IAD. Each section includes probe questions about the presence of obsessions, compulsions, bodily, or preoccupations with health and illness. Next to each probe appear the corresponding DSM diagnostic criteria, which are rated as absent (false), subthreshold, or present (true). Thus, ratings relate to diagnostic criteria rather than interviewees' responses. Relative to the ADIS, the SCID affords the clinician less opportunities to collect qualitative information about patients.

Finally, the *Mini International Neuropsychiatric Interview* (MINI; Sheehan et al., 1998) is a brief

structured interview for the major Axis I psychiatric disorders in DSM-IV. Validation and reliability studies show that the MINI is comparable to the SCID, yet it can be administered in a much shorter period of time than the instruments discussed earlier. Although the MINI can be used to assess the presence of OCD, it does not have modules for assessing BDD or IAD.

### YALE-BROWN OBSESSIVE COMPULSIVE SCALE

The Yale-Brown Obsessive Compulsive Scale (YBOCS; Goodman et al., 1989a, 1989b) is considered the gold standard instrument for assessing the range and severity of OCD symptoms. The scale is divided into three sections. The first section provides definitions of obsessions and compulsions that are read to the patient. The second part contains a rationally derived checklist of over 50 common obsessions and compulsive rituals. The clinician reviews the list with the patient and asks whether her or she is currently experiencing or has ever experienced the symptom. The most prominent obsessions, compulsions, and OCD-related avoidance behaviors are then identified from those endorsed by the patient.

Although the YBOCS checklist is currently the gold standard of assessment for OCD, there are several drawbacks to the measure. First, the YBOCS attempts to be comprehensive in scope, yet it merely assesses the *form* of the patient's obsessions and rituals without examining the relationship between these symptoms. For example, there are no questions relating to how rituals are used to reduce obsessional fears (a functional approach to assessing OCD symptoms that has incremental validity over the YBOCS is described later). Another limitation of the checklist is that it contains too few items assessing some sorts of symptoms (i.e., mental rituals) and includes other items assessing phenomena that are not symptoms of OCD (e.g., self-injurious behavior). Though the YBOCS was primarily developed to assess obsessions and compulsions in OCD, the checklist also contains items that assess BDD (e.g., obsessions about appearance) and IAD (e.g., checking rituals related to somatic obsessions).

The third part of the YBOCS is a severity scale that contains 10 items (5 that assess obsessions and 5 that assess compulsions), each of which is rated on a 5-point scale from 0 (no symptoms) to 4 (extremely severe). Items address (a) the time occupied by current symptoms, (b) interference with functioning, (c) associated distress, (d) attempts to resist obsessions and compulsions, and (e) the degree of control over symptoms. Scores on each of the 10 items are summed to produce a total score ranging from 0 to 40. In most instances, scores of 0 to 7 represent subclinical OCD symptoms, those from 8 to 15 represent mild symptoms, scores of 16 to 23 relate to moderate symptoms, scores from 24 to 31 suggest severe symptoms, and scores of 32 to 40 imply extreme symptoms. The YBOCS severity scale can easily be adapted to assess the severity of BDD and IAD symptoms (and a BDD-YBOCS has been specifically designed to rate the severity of BDD and has demonstrated psychometric validity; Phillips, Hollander, Rasmussen, & Armowitz, 1997). Specifically, the intrusive thoughts (i.e., "somatic obsessions") and compulsive behaviors in these conditions can be rated on the obsessions and compulsions YBOCS items, respectively.

### INSIGHT INTO THE SENSELESSNESS OF SYMPTOMS

The degree of insight a patient has into the senselessness of his or her obsessions and compulsions provides a fair amount of prognostic value for treatment outcome. Therefore, it is extremely useful to assess insight when possible. *The Brown Assessment of Beliefs Scale* (BABS; Eisen et al., 1998) is a seven-item interview that provides a continuous measure of insight into the senselessness of OCD symptoms. It can also be used to assess insight into beliefs about appearance in BDD and beliefs about feared medical conditions in IAD. Administration begins with the interviewer and patient identifying one or two of the patient's specific obsessional fears that have been of significant concern over the past week (e.g., "Everyone thinks I'm ugly because my nose is too big"). Next, specific items assess the patient's (a) conviction in the validity of the fear, (b) perceptions of how others view the validity of the fear, (c) explanation for why others hold a different view, (d) willingness to challenge the fear, (e) attempts to disprove the fear, (f) insight into whether the fear is part of a psychological/psychiatric problem, and (g) ideas/delusions of reference. Only the first six items are summed to produce a total score.

### Self-reported OCD Symptoms

There are a number of self-report instruments available to assess OCD symptoms, yet most are limited by their inclusion of items assessing only the quintessential obsessions and compulsions, failure to adhere to the most recent conceptualizations of obsessions and compulsions as related phenomena,

failure to account for avoidance behavior, or reliance on only a single parameter of severity. The Dimensional Obsessive-Compulsive Scale (DOCS; Abramowitz et al., 2010) is a 20-item self-report measure that addresses most of the limitations of other measures. The DOCS assesses the severity of the four most consistently replicated OCD symptom dimensions (which correspond to the four DOCS subscales): (a) contamination, (b) responsibility for harm and mistakes, (c) symmetry/ordering, and (d) unacceptable thoughts. To accommodate the heterogeneity of OCD symptoms and the presence of obsessions and rituals within each symptom dimension, each subscale begins with a description of the symptom dimension along with examples of representative obsessions and rituals. The examples clarify the form and function of each dimension's fundamental obsessional fears, compulsive rituals, and avoidance behaviors. Within each symptom dimension, five items (rated 0 to 4) assess the following parameters of severity (over the past month): (a) time occupied by obsessions and rituals, (b) avoidance behavior, (c) associated distress, (d) functional interference, and (e) difficulty disregarding the obsessions and refraining from the compulsions. The DOCS subscales have excellent reliability in clinical samples (α = .94–.96) and the measure converges well with other measures of obsessive-compulsive symptoms (Abramowitz et al., 2010).

## Assessment of Patient-specific Symptoms: Functional Analysis

In OCD (and to a lesser extent with BDD and IAD) there is a great deal of individual difference relating to specific fear triggers and strategies for managing anxiety. Therefore, to best understand a particular patient's problems, it is necessary to conduct a thorough investigation of the specific fears and coping mechanisms (i.e., rituals) that are present (e.g., Abramowitz, 2006). The cognitive and behavioral models described earlier provide a framework for collecting this patient-specific information. The collection of such information is critical for deriving a treatment plan. The present section therefore describes the phenomena to be assessed in a functional analysis

### FEAR TRIGGERS

It is important to catalogue all of the external and internal triggers that evoke the patient's obsessional fear. Because of the idiosyncratic nature of fear cues in OCD and related disorders, there is virtually an endless number of potential fear cues. However, triggers typically fall into three domains: situational triggers, intrusive thoughts, and interoceptive cues.

Situational triggers include objects, situations, places, and so on that evoke obsessional fear and general urges to ritualize. In relation to OCD, examples of situational triggers include toilets, knives, completing paperwork, religious icons, feared numbers (e.g., 13 or 666), leaving the house, and so on. In BDD, situational triggers often include looking in the mirror and noticing the perceived disfigurement, social situations, pictures of oneself, and so on. With IAD, triggers are often reminders of the feared illness, such as magazine articles or shows about the illness, hospitals, and so on.

Intrusive thoughts can also trigger obsessional fears across all three of these disorders. As already discussed, in OCD these thoughts are typically unwanted or upsetting images, doubts, or ideas that the person finds unacceptable, intrusive, or disturbing. Examples include images of becoming ill or contaminated, impulses to harm loved ones, thoughts of blasphemy, doubts about one's sexual preference, and thoughts of loved ones being injured. In BDD, intrusions may relate to highly distorted images of how one appears to others. In IAD, the intrusions often focus on the feared medical conditions, such as images of tumors growing inside the body, thoughts about ones' own funeral, doubts about whether the illness is present, and thoughts of missing out on life once one has died.

Bodily sensations may or may not trigger obsessional fear in OCD and BDD, but they clearly play a central role in generating anxiety in IAD. The clinician must therefore learn about all of the internal sensations, feelings, signs, perturbations, and variations of such sensations that trigger health concerns and worries. Specific examples include loose bowel movements, unexplained stomach pain, headaches, feelings of lightheadedness, rapid heartbeat, chest pain, chronic fatigue, sensations associated with respiration or swallowing, and so on.

### COGNITIVE FEATURES

Based on Beck's (1976) idea that anxiety arises from one's beliefs and interpretations of fear cues, information ought to be obtained about the cognitive basis of the individual's fears. This means understanding the consequences the individual associates with the fear triggers (e.g., "I am afraid of public restrooms because I believe I will get AIDS," "If there are 13 at a dinner table, I will have bad luck"). In addition to assessing this

information in a semistructured way (e.g., by asking, "What exactly is it that you fear about _____"), a number of psychometrically sound self-report instruments exist for the purposes of assessing feared catastrophes and the dysfunctional beliefs that underlie them. For example, the Obsessive Beliefs Questionnaire (OBQ; OCCWG, 2005) and Interpretation of Intrusions Inventory (III; OCCWG, 2005) assess cognitions found to be related to OCD. Analogous measures, the Short Health Anxiety Inventory (SHAI; Salkovskis et al., 2002) and Cognitions About Body and Health Questionnaire (CBHQ; Rief et al., 1998), have been developed to measure key dysfunctional cognitions in IAD. Unfortunately, no such measure is presently available for individuals with BDD.

## AVOIDANCE STRATEGIES

In an attempt to prevent feared catastrophes, most individuals with OCD, BDD, and IAD avoid situations and stimuli that may trigger their fears and obsessions. Avoidance might be overt, such as the evasion of certain people (e.g., cancer patients, the homeless, popular people), places (e.g., public washrooms, hospitals, school), situations (e.g., using pesticides, giving oneself a breast exam, going to a party), or certain words (e.g., "sex," "cancer"). Alternately, avoidance can be more subtle, such as staying away from the *most often touched* part of the door handle and refraining from listening to *loud* music while driving. In addition to understanding *what* the person is avoiding, it is important to assess *why* he or she avoids it. For example, a man with extreme illness anxiety avoided giving himself testicular exams because he worried he might discover that he has testicular cancer. A young woman with BDD avoided public places because she felt others would be staring at her disproportionately sized breasts. A man with OCD refused to listen to the radio while driving because he felt it would distract him and cause him to hit pedestrians.

## COMPULSIVE RITUALS

The frequently ubiquitous nature of the external stimuli, intrusive thoughts, and bodily sensations associated with OCD and related conditions can make triggers difficult to successfully avoid. Thus, patients use rituals as "active avoidance" strategies that provide a means of *escape* from fear which could not be avoided. Often these rituals are overt behaviors performed repetitively and in accordance with certain self-prescribed rules (e.g., checking exactly 10 times, washing for 40 seconds). Other rituals may be more subtle, brief, or performed only mentally (e.g., holding the steering wheel tightly, compulsive praying, wearing makeup to cover up a blemish, etc.). As with avoidance, the clinician should assess the function or purpose of the ritual: Why does the person need to perform the behavior at all and what consequence does the person fear would occur as a result of failing to perform the ritual?

## SELF-MONITORING

Self-monitoring is an information-gathering strategy in which the clinician asks the patient with OCD, BDD, or IAD to record the occurrence of rituals in "real time." Specifically, the clinician instructs the patient to log the following parameters using a form with corresponding column headers: (a) the date and time of the ritual, (b) the fear trigger (situation, thought, bodily sensation) that evoked anxiety and the need to ritualize, and (c) a description of the ritual itself, and (d) the length of time spent performing the behavior. Self-monitoring helps the clinician and patient gain a clearer picture of the way in which (obsessional) fear and rituals are related, and how much time is consumed by such episodes. Figure 16.1 contains an example of one patient's OCD self-monitoring form.

## Treatment

In this section, we discuss empirically supported psychological treatments for OCD, BDD, and

| Date and time | Activity or thought that triggered the ritual | Ritual | Time ritualizing |
| --- | --- | --- | --- |
| June 11 at 8:05 | Taking out the garbage | Hand washing | 1 min 45 sec |
| June 11 at 9:30 | Leaving the house for work | Checking electrical appliances | 23 min |
| June 11 at 12:15 | Intrusive thought that my house is on fire | Go home to check the house | 45 min |
| June 11 at 3:35 | See a red spot on the carpet, thoughts about blood | Change clothes and shower | 30 min |

**Figure 16.1** Self-monitoring form from an individual with OCD

hypochondriasis/IAD. These interventions are generally based in the behavioral and cognitive traditions as described earlier. The procedures for each individual intervention are delineated, and then a brief review of the supporting research is presented.

Before the 1960s, OCD was largely considered treatment resistant. The most widely used intervention was psychodynamic psychotherapy in which the therapist attempted to determine the "root" cause of the patient's obsessions and compulsions by uncovering evidence of unconscious conflict. Although BDD did not exist as an official diagnosis until the publication of DSM-III-R (APA, 1987), unrealistic concerns about appearance were addressed in a similar fashion. IAD, then called hypochondriasis, had been well known for centuries and was often conceptualized as pathological attention-seeking behavior (i.e., for being in the sick role) and was dealt with via similar therapeutic approaches. Unfortunately, there is little systematic research on the efficacy of psychodynamic treatment approaches. However, the fact that OCD was considered treatment refractory suggests psychodynamic therapy was generally ineffective in producing long-term treatment gains.

### Exposure-based Therapy

Troubled by the disappointing results of psychodynamic treatments, behaviorally oriented clinical researchers in the 1960s and 1970s began to apply learning and conditioning models to the treatment of fear-based problems such as OCD. Victor Meyer (1966) is credited with being the first to report a systematic study of the effects of behavioral treatment for OCD. Meyer encouraged patients hospitalized with OCD to deliberately confront, for 2 hours each day, situations and stimuli they usually avoided (e.g., toilets, door knobs). The purpose of this confrontation was to induce obsessional fears and urges to perform compulsive rituals. Once such fears and urges were elicited, patients were instructed to refrain from performing their rituals (e.g., no washing or cleaning allowed). Ten of Meyer's 15 patients responded extremely well to this therapy and the remainder showed partial improvement. Follow-up studies conducted several years later found that only two of those who were successfully treated had relapsed (Meyer, Levy, & Schnurer, 1974). These techniques would eventually be adopted worldwide and become known as exposure and response prevention (i.e., ERP).

Contemporary ERP, which is used (at least in part) in the treatment of OCD, BDD, and IAD, entails therapist-guided systematic repeated and prolonged exposure to the fear triggers identified during the functional assessment. Abstinence from compulsive and ritualistic behaviors is also required. This might occur in the form of repeated (a) actual confrontation with feared but objectively low-risk situations (i.e., in vivo exposure), (b) imaginal confrontation with anxiety-provoking intrusive thoughts and images (imaginal exposure), or (c) deliberate provocation of distressing (but harmless) internal bodily sensations (interoceptive exposure; e.g., drinking caffeine to produce feelings of jitters, or squinting one's eyes to provoke a tension headache). In the case of an individual with OCD who has contamination obsessions triggered by restrooms, the patient would practice touching restroom surfaces such as doorknobs, toilets, and sinks. Generally the patient would be asked to work her way up from touching less disturbing surfaces (e.g., walls and doorknobs) to more disturbing surfaces (e.g., flush handles, toilet seats, and even the interior of the toilet bowl). She might also practice imaginal exposure to the idea of having "restroom germs" on her hands and then spreading these germs and becoming ill. For someone with BDD, exposure might entail not wearing any makeup and going to a social event. For a person with fears of leukemia as part of his IAD, exposure might entail reading a book about leukemia sufferers and imagining having the disease (or at least not knowing for sure whether he has it).

Refraining from compulsive rituals (response prevention) is a vital component of effective treatment because the performance of rituals to reduce fear would prematurely discontinue exposure and consequently prevent the patient from learning that (a) the fear trigger is not realistically dangerous, (b) anxiety subsides on its own even if the ritual is not performed, and (c) the temporary feelings of fear and anxiety are manageable. Thus, successful ERP requires that the patient remain in the exposure situation, despite experiencing anxiety or distress, and without using standby rituals to artificially reduce the distress via avoidance or escape. Continuing on with the exposure examples earlier, the person with OCD would refrain from washing or showering, the person with BDD would refrain from checking or applying makeup, and the person with hypochondriasis would resist the urge to seek reassurance or additional medical testing about whether he has leukemia.

Practically speaking, the therapist typically supervises exposure therapy practices during the

treatment session and then assigns additional exposure practices (usually similar to that practiced within the session) to be completed as homework. Depending on the individual's specific fear triggers and the practicality of confronting actual feared situations, treatment sessions might involve varying amounts of actual, imaginal, and interoceptive exposure practice.

Treatment usually begins with a functional assessment as described earlier. Before actual treatment begins, the therapist also provides the patient with a clear rationale for how ERP is expected to be helpful in reducing obsessional and compulsive symptoms. This is an important step in therapy because it helps to motivate the patient and increase his or her tolerance to the distress that typically accompanies exposure practice. A helpful rationale includes information about how ERP involves learning new information about the feared situation (i.e., that it is not as dangerous as is thought and that anxiety is manageable) that cannot be learned if avoidance and rituals are performed. Information gathered during the assessment is then used to plan, collaboratively with the patient, the specific exposure exercises that will be pursued.

In addition to explaining and planning a list or "hierarchy" of exposure exercises, the educational stage of ERP must also acquaint the patient with response prevention procedures. Importantly, the term "response prevention" does not imply that the therapist actively *prevents* the patient from performing rituals. Instead, the therapist must convince patients to resist urges to perform rituals on their own. Self-monitoring of rituals is often used in support of this goal.

The exposure exercises typically begin with at least moderately distressing situations, stimuli, and images, and escalate to increasingly distressing situations. The full hierarchy of stimuli should be confronted during treatment. Beginning with moderately (as opposed to very highly) anxiety-evoking exposure tasks increases the likelihood that the patient will learn that anxiety is manageable and complete the exposure exercise successfully. Moreover, having success with initial exposures increases the patient's confidence in the treatment and reduces the likelihood of treatment dropout. At the end of each session, the therapist instructs the patient to continue exposure for several hours and in different environmental contexts, without the therapist. Practicing in different contexts allows for the generalization of treatment effects. During the later treatment sessions, the therapist emphases the

importance of continuing to apply the ERP procedures learned during treatment. The details of how to use ERP in the treatment of OCD, BDD, and IAD can be found in resources such as Abramowitz (2006), Wilhelm, Phillips, and Steketee (2013), and Abramowitz and Braddock (2008), respectively.

## HOW DOES ERP WORK?

First, from a conditioning perspective, ERP provides an opportunity for the extinction of conditioned fear responses. Extinction occurs when the once-feared obsessional stimulus is repeatedly paired with the nonoccurrence of feared consequences and the eventual reduction of anxiety. Research suggests that fear associations are not removed during extinction, but rather remain intact as new learning about the feared stimulus occurs (e.g., Bouton & King, 1983; Craske et al., 2008). That is, following successful ERP, the feared stimulus is thought to possess two meanings: the original excitatory (i.e., fear-based) meaning as well as an inhibitory ("safety-based") meaning. Thus, even if fear subsides following successful exposure, the original excitatory meaning is retained and may be recovered under certain circumstances such as a change in context, the passage of time, and reacquisition of the original association (Bouton, 2002). Accordingly, the extinction that occurs during ERP is the result of *inhibitory learning*—patients learn new nonthreat associations and ways of enhancing the accessibility of these new associations (relative to the older threat associations) in different contexts and over time.

Foa and Kozak (1986) proposed three necessary conditions for (and indicators of) extinction during exposure-based treatment: First, that physiological arousal and subjective fear must be evoked during exposure; second, that fear responses gradually diminish *during* the exposure session (within-session habituation); and third, that the initial fear response at the beginning of each exposure session declines *across* sessions (between-sessions habituation). Research, however, does not uniformly support these assertions. That is, neither initial fear activation nor habituation (within or between exposure sessions) is a consistent predictor of therapeutic outcome with exposure (Craske et al., 2008). Instead, Craske and colleagues argue for considering fear *toleration*, rather than immediate fear *reduction*, as a primary goal of exposure therapy.

From a cognitive perspective, ERP is effective because it corrects dysfunctional beliefs that underlie fear and anxiety by presenting the patient with disconfirmatory evidence. For example, when a patient

confronts feared situations and refrains from rituals, he or she finds out that fear/anxiety is manageable (and often declines naturally) and that the anticipated negative consequences of confrontation with the feared stimulus are unlikely. This evidence is processed and incorporated into the patient's belief system. Thus, rituals to reduce anxiety and prevent feared disasters become unnecessary. Finally, patient are thought to gain self-efficacy through ERP by finding out that they can master their fears without having to rely on avoidance or compulsive rituals. The importance of this sense of mastery is an often overlooked effect of ERP.

#### EFFICACY OF ERP

Most of the research examining the effects of ERP has been conducted with OCD. A meta-analysis of 24 ERP studies revealed very large posttreatment (ES = 1.16 to 1.41) and follow-up (ES = 1.10 to 1.57) effect sizes (Abramowitz, 1996). Furthermore, it has been demonstrated that the majority of OCD patients who undergo treatment with ERP evidence substantial short- and long-term benefit (Foa & Kozak, 1996). Data from individual studies reveal that patients who complete a trial of ERP consistently achieve 50% to 70% symptom reduction.

A number of carefully designed controlled studies have also provided particularly strong evidence of the superiority of ERP over credible control therapies such as progressive muscle relaxation training (e.g., Fals-Stewart, Marks, & Shaffer, 1993), anxiety management training (Lindsay, Crino, & Andrews, 1997), autogenic self-relaxation training (Nakatani et al., 2005), and pill placebo (Foa et al., 2005). These studies indicate that the effects of ERP are due to the specific ERP techniques over and above the effects of nonspecific factors common to all interventions, such as the therapeutic relationship. Of particular interest, ERP has also been found more effective than antidepressant medications used in the treatment of OCD (e.g., Foa et al., 2005). For patients receiving ERP, symptom reductions typically exceed 50%–60%. However, most patients evince mild to moderate residual symptoms. Therefore, despite clinically significant improvement in symptoms, patients with OCD rarely achieve complete symptom remission with ERP. More recent efficacy studies are working to maximize the cost effectiveness of ERP by using a stepped-care administration in order to reduce treatment costs without sacrificing efficacy or patient satisfaction (Tolin, Diefenbach, & Gilliam, 2011). The effects of ERP are not limited to highly selected research samples or to treatment as delivered in specialty clinics, moreover. Effectiveness studies conducted with nonresearch patients (e.g., Franklin, Abramowitz, Foa, Kozak, & Levitt, 2000) additionally show that over 80% of patients who complete ERP achieve clinically significant improvement.

Only a handful of studies have examined the effects of ERP for BDD (e.g., Campsi, 1995) and hypochondriasis (e.g., Taylor, Asmindson, & Coons, 2005). Three reviews of the BDD literature suggest that ERP produces large effects from pre to posttreatment that are comparable to the effects of ERP for OCD, with posttest scores on a version of the Y-BOCS adapted for BDD typically in the "moderate" range (Cororve & Gleaves, 2001; Greenberg & Wilhelm, 2011; Williams, Hadjistavropoulous, & Sharpe, 2006). Reviews have concluded that exposure therapy for BDD generally performs better than wait-list control treatment and is associated with not only BDD symptom reduction but also improvement in related symptoms of functioning, depression, anxiety, and delusional beliefs (Greenberg & Wilhelm, 2011). A recent pilot study demonstrates promising feasibility, acceptability, and efficacy of a new modular CBT treatment for BDD (Wilhelm, Phillips, Fama, Freenberg, & Steketee, 2011).

The efficacy of ERP for hypochondriasis is demonstrated by a number of small trials (Logsdail et al., 1991; Visser & Bouman, 1992; Warwick & Marks, 1988). Several larger controlled studies have also found CBT for hypochondriasis to be significantly more effective than a wait-list control condition, medical care as usual, and pill placebo (Barsky & Ahern, 2004; Greeven et al., 2007; Visser & Bouman, 2001). In the most recent of these studies, 54% of CBT completers were identified as responders (patients whose posttest scores were one standard deviation or more below the pretest mean and whose reliable change score exceeded the measurement of error) versus 38% who received paroxetine, versus 12% who received a pill placebo (Greeven et al., 2007). In a meta-analytic review by Taylor et al. (2005), ERP was associated with large short- and long-term effect sizes; however, this estimate included only two studies.

### Cognitive Therapy

Although often effective, ERP depends upon patients making the decision to face their fears and provoke anxiety and then to resist using the coping strategies which have become entrenched as fear reduction crutches. Needless to say, this is a

daunting proposition and many individuals with OCD and related disorders refuse ERP or discontinue treatment prematurely. Consequently, some clinicians and researchers have turned to cognitive therapy (CT) approaches that incorporate less prolonged exposure to fear cues and have proven useful in the treatment of other anxiety disorders such as panic disorder and social phobia. CT chiefly involves the rational and evidence-based challenging and correction of faulty and dysfunctional thoughts and beliefs that are thought to underlie pathological fear (e.g., Clark, 1999). In practice, some behavioral techniques (i.e., ERP) are commonly implemented alongside of CT strategies. The term *cognitive-behavioral therapy* (CBT) was coined in response to the notion that CT and ERP are complementary because they both affect change on behavioral and cognitive levels.

As with ERP, CT begins with the therapist presenting a rationale that incorporates Beck's (1976) cognitive specificity model—the concept that one's *beliefs and appraisals* of situations and stimuli (not the situations and stimuli themselves) determine how one feels and acts. Patients are taught to examine their own beliefs and appraisals and appreciate how beliefs and interpretations influence their emotions and behaviors. Additionally, they are taught how modifying (or *correcting*) faulty beliefs and appraisals can help to alleviate their problems with anxiety and rituals (Wilhelm & Steketee, 2006).

Psychoeducation is an important part of CT because it is assumed that anxious patients lack objective knowledge about the true danger (or safety) of feared stimuli. For instance, in OCD, psychoeducation focuses on teaching the patient that his or her obsessional thoughts are in fact harmless—for example, they are not signs of moral failing. Patients are taught to understand how misappraisal of such intrusions leads to preoccupation with the unwanted thought as well as responses, such as avoidance and compulsive rituals, which unwittingly maintain the obsessional preoccupation and anxiety. In an analogous fashion, individuals with IAD are taught about the ubiquity of bodily sensations (e.g., Abramowitz & Braddock, 2008; Taylor & Asmundson, 2004).

Various techniques are used to help patients correct their erroneous beliefs and appraisals, such as didactic presentation of educational material, Socratic dialogue aimed at helping patients recognize and correct dysfunctional thinking patterns, and gathering objective evidence about feared stimuli through "behavioral experiments," in which the

patient tests out the validity of his or her beliefs. An example of a cognitive technique used in the treatment of OCD is the "pie technique" (Clark, 2004), which involves the patient giving an initial estimate of the percent responsibility which would be attributable to him or her if a feared consequence were to occur. Next, the patient generates a list of the parties (other than himself/herself) that would also have some responsibility for the feared consequence. The patient then draws a pie chart, each slice of which represents one of the responsible parties identified. Finally, the patient labels all parties' slices according to their percent responsibility and labels his or her own slice last. By the exercise's end, it is generally clear to patients that the majority of the responsibility for the feared event would not be their own.

For someone with BDD, a behavioral experiment might involve having a conversation with someone and noticing how much the other person appears preoccupied with the imagined defect or how often the other individual stares at the imagined flaw. When these feared consequences do not occur (or occur less than anticipated), this can be used to help the patient reevaluate the accuracy of his or her appearance-related beliefs. In the case of IAD, a behavioral experiment might involve delaying reassurance seeking about bodily sensations to see that these sensations are manageable and naturally dissipate with time. Such a technique can be used to change catastrophic misperceptions of such sensations as malignant or long term. This latter experiment resembles the type of interoceptive exposure and response prevention often used for individuals with panic disorder. In turn, this raises the point that although there is some procedural overlap between many behavioral experiments and ERP, conceptually, these techniques are different. Behavioral experiments are primarily aimed at modifying dysfunctional beliefs, whereas ERP exercises are traditionally intended to bring about extinction of classically conditioned fear.

## EFFICACY OF CT

A handful of studies have addressed the relative efficacy of CT and ERP by directly comparing the two interventions. Although the results of these studies have largely been that ERP and CT have similar effects (Belloch, Cabedo, & Carrió, 2008; Cottraux et al., 2001; Emmelkamp & Beens, 1991; van Oppen, van Balkom, de Haan, & van Dyck, 2005; Whittal, Thordarson, & McLean, 2005), methodological issues cloud the ability to draw strong conclusions from them. For instance, in

several of these comparison studies, ERP and CT both yielded only minimal improvements (e.g., 30%–40% symptom reduction; a great deal less than is typical for ERP). One explanation for this is that in some studies, exposure practice was conducted exclusively for homework without therapist supervision, thus making for a suboptimal exposure intervention. Moreover, the CT programs in the aforementioned studies could have been enhanced by in-session behavioral experiments that likely have similar effects as supervised exposure. Using meta-analytic methods, Abramowitz, Franklin, and Foa (2002) found that behavioral experiments improve the efficacy of CT for OCD. In other studies of OCD that incorporated in-session exposure within ERP protocols, the treatment based on behavioral theory appears to be superior to CT. Vogel, Stiles, and Götestam (2004) found that the inclusion of CT was useful in reducing dropout from ERP. Thus, there are likely benefits to incorporating CT techniques in addition to ERP; perhaps CT techniques improve the acceptability of ERP.

A small number of case reports and controlled studies suggest that CT (some involving behavioral techniques; i.e., CBT) can be effective for BDD (e.g., Rosen et al., 1995). More recently, Khemlani-Patel, Neziroglu, and Mancusi (2011) found that in a modest sample of patients with BDD, adding cognitive therapy to ERP did not significantly enhance the effects of ERP alone, similar to the studies reported earlier on patients with OCD.

There is strong evidence that CBT, which combines CT and exposure techniques, is an effective treatment for hypochondriasis (Taylor, Asmundson, & Coons, 2005). Several controlled studies demonstrate clinically significant and lasting improvements (e.g., Barsky & Ahern, 2004; Clark et al., 1998; Visser & Bouman, 2001). In a wait-list controlled study, Warwick and colleagues (1996) found that CBT produced significant reductions in reassurance seeking, overall health anxiety, and checking frequency. General anxiety was reduced by approximately 70%, and depressive symptoms, by 53%. Moreover, CBT was acceptable to patients: Only 6% of those recruited into the study refused to begin therapy, and another 6% dropped out of treatment prematurely.

In a study evaluating the relative effects of CT and ERP for hypochondirasis, Visser and Bouman (2001) found that both treatments produced significant improvement relative to waiting list, and immediately following treatment, there were no differences between ERP and CT. Improvement was also durable: At the 7-month follow-up assessment, patients remained improved, with no significant differences between active treatments. Thus, the available evidence does not suggest substantial differences in the efficacy of ERP and CT approaches for hypochondriasis. As discussed earlier with respect to OCD, a likely explanation for this is that these treatments incorporate elements of one another. That is, the effective implementation of ERP requires the implicit modification of dysfunctional beliefs that underlie anxiety and fear; and CT typically involves exposure-like behavioral experiments in which patients confront feared situations to disconfirm dysfunctional beliefs and attitudes (Deacon & Abramowitz, 2004).

## Conclusion

In the last hundred years a great deal of progress has been made toward understanding the nature and origin of OCD and developing effective treatment for this condition. Following a firm push by some members of the research community (albeit a minority), there now exists a DSM diagnostic category of obsessive-compulsive related disorders encompassing OCD and several conditions thought to be strongly related to it. While superficially it may seem appealing to conceptualize problems such as pathological hair pulling, hoarding, and skin picking as variants or relatives of OCD, a deeper investigation of the relationship between such problems and OCD reveals a cosmetic relationship at best. On the other hand, BDD and IAD do appear to be meaningfully related to OCD both in terms of symptom presentation and treatment response (although IAD is not included as an OCRD in DSM-5). Regardless of how they are categorized in DSM-5, cognitive and behavioral models of OCD, BDD, and IAD provide an empirically consistent account of the maintenance of these conditions; and researchers are working toward better understanding their (likely multifaceted) etiologies. Diagnostic tools, assessment strategies, and treatments based on research in the cognitive and behavioral traditions have also proven successful in properly identifying affected individuals, targets of treatment, and alleviating the symptoms of these disorders. Moreover, procedures such as ERP and CT, which operate on the psychological mechanisms that maintain these disorders, rather than the disorders per se, have demonstrated success in producing both short- and long-term treatment gains for those suffering with OCD, BDD, and IAD.

# Somatoform and Physical Disorders

Robert L. Woolfolk *and* Lesley A. Allen

## Abstract

This chapter provides an overview of the treatment of somatoform and related disorders. A brief history of the disorder is provided, along with a sociocultural framework in which to conceptualize somatization. The epidemiology of somatoform disorders is discussed. Empirical research evaluating psychosocial treatments for somatoform disorders, including the functional somatic syndromes, is reviewed and critiqued. The rather substantial assortment of treatment options available to clinicians is compared and contrasted, and their level of empirical support evaluated. The limitations of the empirical literature, as well as the treatment implications that can be drawn, are discussed.

**Key Words:** Cognitive-behavioral therapy, functional somatic syndromes, medically unexplained physical symptoms, mind-body, psychosomatic, psychotherapy, somatization, somatoform

Somatization is among the most puzzling phenomena that health-care workers encounter. In somatization, physical symptoms occur in the absence of any identifiable bodily mechanism. The causes of somatization that we are able to implicate are neither proximate nor identifiably somatic. Patients presenting with medically unexplained physical symptoms (MUPS) provide significant challenges to health-care providers. These patients tend to overuse health-care services, derive little benefit from treatment, and experience protracted impairment, often lasting many years (Smith, Monson, & Ray, 1986a). Often, MUPS patients are dissatisfied with the medical services they receive and repeatedly change physicians (Lin et al., 1991). These "treatment-resistant" patients frustrate physicians with their frequent complaints and dissatisfaction with treatment (Hahn, 2001; Lin et al., 1991). Because standard medical care has been relatively unsuccessful in treating somatoform and factitious disorders, alternative treatments have been developed.

The chapter summarizes and evaluates the treatment of various somatoform and factitious disorders.

All the somatoform and factitious disorders are characterized by the presence of physical symptom(s) that suggest a general medical condition but are not fully explained by a general medical condition. Somatoform disorders differ from factitious disorders in the extent to which the symptoms are intentionally produced or feigned. Symptoms related to a factitious disorder are intentionally produced or feigned in order to assume the sick role. Symptoms related to a somatoform disorder are not under voluntary control.

## Background: Historical and Theoretical

The history of somatization begins with hysteria, first described 4,000 years ago by the Egyptians and later elaborated and named by the Greeks. Typical cases involved pain in the absence of any injury or pathology in the location of the pain. The Greco-Egyptian formulation reveals two noteworthy features: that the disorder was primarily observed in females, and that there was something thought to be essentially female about the disorder. Foucault (1961/1965) suggests that, by the end of the 18th century, hysteria

and hypochondria were beginning to be viewed as "diseases of the nerves," akin to such recognized mental disorders as melancholia. Before the 19th century, because of the heterogeneous nature of hysterical symptoms and the hypothesized connection with the emotions, physicians had begun to allege that these symptoms were feigned or imagined (Woolfolk & Allen, 2007). The unsympathetic attitudes of contemporary health-care workers toward somatizers and the tendency to regard these patients as malingerers can be traced to this period in the history of medicine.

A landmark in the descriptive psychopathology of somatization was the seminal monograph of Paul Briquet (1859), *Triate Clinique et Thérapeutique de L'hysterie.* Our current conception of somatization disorder derives directly from this paper. Briquet's meticulous and exhaustive listing of the symptomatology of hysteria remains unsurpassed. Briquet, in fact, described three related syndromes: conversion phenomena, hysterical personality, and multiple chronic unexplained somatic symptoms (Dongier, 1983; Mai & Merskey, 1980). These three syndromes overlapped in symptomatology somewhat, and they often were observed to co-occur. Briquet's perspicuous work was revived by Purtell, Robins, and Cohen (1951) and developed further by members of the illustrious Washington University department of psychiatry. Perley and Guze (1962) published a list of 57 symptoms, commonly reported by women diagnosed with hysteria, symptoms that were clustered in ten different areas. These investigators were the first to suggest specific criteria for the diagnosis of hysteria: the presence of 25 symptoms from at least nine of the ten symptom areas (Guze, 1967). Later, this list of 57 symptoms was expanded to include 59 symptoms and the term *Briquet's syndrome* was adopted (Guze, Woodruff, & Clayton, 1972). The criteria for Briquet's syndrome were incorporated into the Feighner criteria (Feighner, Robins, Guze, Woodruff, Winokur, & Munoz, 1972), the precursor to the symptom set that appeared in the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III; American Psychiatric Association [APA], 1980). In that volume, the theoretically neutral term, *somatization*, was preferred over the more traditional terminology. Although some of the traditional language remains in the fourth edition of the DSM (e.g., "conversion disorder"), the word "hysteria" no longer appears (DSM-IV; APA, 1994). The ninth edition of the World Health Organization's International Classification of Diseases (ICD-9; WHO, 1979), a more cosmopolitan nosology of somatic and mental disorders published a year earlier than DSM-III, retains much of the perennial terminology, including not only hysteria but also "neurasthenia."[1] ICD-10 (World Health Organization, 1993) has shifted in the direction of the American volume, although without banishing every bit of the classical vocabulary.

## Psychodynamic Roots

Many of Sigmund Freud's early patients were hysterics. His first book, co-authored with Breuer, was entitled *Studies in Hysteria* (1895/1974), in which Breuer and Freud developed the concept of "conversion," a process whereby intrapsychic activity putatively brings about somatic symptoms. This work also introduced the notion of a physical symptom as an unconscious form of communication, as a device for securing secondary gain, or as a means for avoiding emotional pain.

Franz Alexander (1950) was a contributor to the psychoanalytic literature and an important figure in what was, in the mid 20th century, called "psychosomatic medicine." He distinguished between two types of psychosomatic symptoms: those cases in which psychological conflict was "converted" and communicated symbolically through physical symptoms, and those cases in which the somatic symptoms resulted from the direct and indirect physiological effects of emotional arousal. This second kind of psychosomatic mechanism required few, if any, psychoanalytic assumptions and was quite compatible with mainstream scientific research, especially the work of Cannon, Seyle, and others on psychosocial stress. As psychoanalysis declined in influence, psychosomatic medicine declined also. Today, the term "psychosomatic," which was faddish in the 1950s, is no longer in vogue. Many of the problems once treated within the context of psychosomatic medicine now fall under the purview of what is, in some sense, its successor discipline, behavioral medicine.

---

[1] ICD-10 *Neurasthenia* is defined as persistent and distressing feelings of exhaustion after minor mental or physical effort accompanied by one or more of the following symptoms: muscular aches or pains, dizziness, tension headache, sleep disturbance, inability to relax, and irritability. The term was coined in 1856, by Robert Mayne and popularized by the American neurologist George Beard during the second half of the 19th century (Gijswijt-Hofstra & Porter, 2001).

## Sociocultural and Conceptual Issues

Historically, in Western psychiatry, a mental disorder has been posited in one of two instances. The first of these occurs when there exists a theory of psychogenesis, such as psychoanalysis, that hypothesizes mental entities to be the underlying causes of the symptoms of a disorder. The second instance involves the presence of symptoms in the absence of a physicalistic explanation. In this second instance, psychogenic etiology may be inferred solely from the absence of a known underlying physical mechanism, thus revealing a tacit dualism that originated even before Paracelsus and that continues to underlie Western medicine: Disease entities, whether they be causes or symptoms, belong to one and only one of two categories, either the physical or the mental—these two categories being mutually exclusive (Robinson, 1996). Symptoms of almost any variety that cannot be linked to a scientifically explained physical pathology are assumed to be psychogenic. Individuals afflicted with multiple sclerosis, Wilson disease, temporal lobe epilepsy, and numerous other maladies currently within the purview of somatic medicine were once regarded as mentally ill. Through the course of medical progress, mental illness has served as a residual category wherein poorly understood or refractory illness has been placed, often temporarily, only to exit when medical science established the physical mechanisms underlying the disorder (Grob, 1991).

Dualistic assumptions operate not so subtly within DSM-IV. In DSM-IV, two principal classes of disease entities are posited: general medical conditions and primary mental disorders. Contradistinct from the most paradigmatic mental disorders contained in DSM-IV are mental symptoms resulting from a "general medical condition" (read physical illness). Such symptoms arising from such causes, indeed, imply the absence of a mental disorder. Of course, DSM-IV's authors claim that the distinction between primary mental disorders and those stemming from a general medical condition should not be taken to imply that there are fundamental differences between mental disorders and general medical conditions (APA, 1994, p. 165). But the volume is careful to distinguish symptoms deriving from a general medical disorder from those that emanate from a primary mental disorder. This distinction is drawn so sharply that symptoms of organic origin are exclusionary for the diagnosis of such paradigmatic disorders as schizophrenia. The locution of the volume instantiates not only dualism, but also logical circularity, in that a general medical condition is defined as a medical condition other than a primary mental disorder, and a primary mental disorder is defined as something other than the result of a general medical condition. The distinction drawn here, whether nominal or substantive, is old Cartesian wine in a new bottle, that venerable distinction between the functional and the organic. In its language, DSM-IV also stipulates, as a kind of axiom, the historical role of psychiatry as a processor of aberrations within the category of illness. Mental illnesses are abnormal, poorly understood illnesses that normal physicians do not treat.

The biopsychosocial concept of illness, proposed by George Engel (1977) and to which the authors of this chapter subscribe, suggests that illness is a complex entity involving the interplay of physical, psychological, and cultural factors. In particular, many illnesses cannot be adequately comprehended without taking into account the social contexts in which they develop, are manifested, diagnosed, and treated. What phenomena that societies come to label "illness" or how human suffering is expressed and presented to healers are complicated matters that can be conceptualized at several different levels, levels that involve variables that interact causally.

Research on psychopathology in countries outside of North America and Europe frequently is used to argue that cultural factors are crucial in determining the manner in which human suffering is experienced and, more specifically, to support the view that non-Western societies are prone to generate somatic expressions of distress. One distinction that is made in cross-cultural theory is that between somatization and "psychologization." The former refers to the experience of bodily aspects of distress, whereas the latter refers to the experience of the psychic, social, and mental aspect of distress (Kirmayer, 1984; White, 1982). According to this formulation, either somatization or psychologization could serve as alternative modalities through which a negative emotional reaction is experienced and as alternative "idioms of distress" through which emotional pain is communicated. It has been suggested that psychologization is compatible with Western, Euro American concepts of selfhood and with an individualistic, psychologically minded world view that emphasizes causal explanations implicating individual persons and their traits as sources of events (Kihlstrom & Canter Kihlstrom, 1999; Kirmayer, Young, & Robbins, 1994). Somatization, in contrast, has been associated with the more sociocentric cultural views of selfhood, wherein self-reflection and self-examination are de-emphasized or disvalued; here, behavior is more often viewed as caused by the external environment,

rather than by qualities of the person, such as psychological traits or will-power. Other factors that might influence the ratio of psychologization to somatization are the stigma attached to psychological symptoms and the degree to which a desired treatment is obtained through either a psychological or a somatic presentation (Kirmayer, 2001). According to this view, a culture's background assumptions about illness or its "idiom of distress" is crucial to determining whether a disruption of homeostasis is experienced as physical rather than mental. An individual can learn to attend to and express physical discomfort, rather than psychological distress, especially if an idiom of affect is not available. Thus, the theory has it that somatization conditions can be shaped through processes of selective attention to physical symptoms and by learning a vocabulary of somatic symptomatology.

Whether there are cultures that foster somatization is still a complex and controversial question. The World Health Organization's international collaborative study of Psychological Problems in General Health Care (Gureje, Simon, Ustun, & Goldberg, 1997) did not find the disparity in somatization disorders between East and West that might have been predicted from the early formulations of medical anthropologists. Nor did the ratio of somatic to psychological symptoms of depression vary across cultures in a systematic or expected fashion. However, the data were, to some degree, consistent with the cultural hypothesis. For example, somatization rates were significantly higher in Latin America than in the rest of the world, and rates of somatization were higher in China than in the United States (Simon, VonKorff, Piccinelli, Fullerton, & Ormel, 1999). Cultural variation in psychopathology results not only from differences in how psychiatric labels are applied, but from the fact that different societies seem to produce different forms of psychopathology. Many specific syndromes are unique to particular cultural contexts, such as *ataque de nervios*, *koro*, or *taijin kyofusho*.[2] The epidemics of anorexia nervosa and bulimia in the contemporary West are unprecedented, but are spreading to middle and upper classes around the world, along with Westernization and its current aesthetic ideal of a slender female body (Ung & Lee, 1999). Writers such as Ian Hacking (1995; 1999) have argued persuasively that some mental disorders (e.g., multiple

personality disorder) are roles that are created by the theories and practices of the mental health professions and subsequently enacted by patients. The articulation and dissemination of information about psychopathology through professional activities and by the media provide a symptom set and patient profile that can be assimilated by disturbed individuals who possess sufficient psychic malleability (Woolfolk, 1998).

**Models of Somatization**
It has not been since the psychoanalytic era that somatization was viewed as a well-understood phenomenon. In some sense, we have not progressed very far beyond Breuer and Freud's psychodynamic theory of conversion hysteria. Currently, there is widespread admission among authorities that no adequate theory of somatization exists. Indeed, one might argue that, with the exception of the oft-criticized and scientifically beleaguered psychoanalytic theory, there are no well-developed theories of somatization, rather merely some fragmentary models or speculation.

In evaluating models of somatization, one needs to be mindful of the logical pitfalls that abound in the territory of mind–body relationships. As we have seen in conjecture about the cause of somatization, such phrases as "emotional distress expressed as physical symptoms" or a "somatic idiom of distress" or a tendency to "somatize rather than psychologize" are invoked. Such locutions are problematic and bespeak the poverty of our theories, as they invariably risk the possibility of emerging as either pseudo-explanatory or tautologous. Such formulations often fail to explain because they leave key terms undefined and unexplained. We have seen this kind of fallacious logic before in psychiatric discourse that utilizes the notion of "chemical imbalance" in explanations of the treatment of depression (i.e., a prior chemical imbalance being inferred from a presumptive "balancing" of neurochemistry by antidepressants). Key concepts that are unexplained can result in circular reasoning, illustrated by Moliere's physician who attributed the effect of a soporific to its "dormative powers." A cogent explanation of somatization must spell out exactly what is denoted by the "emotional distress" that is putatively "expressed" somatically and also include valid and reliable methods for measuring it. Can the emotional distress thought to underlie somatization be identified independently of the somatic expression of it? If not, what is the epistemological status of our model or theory? Are we simply assuming a priori that there is some

---

[2] Each of these "culture specific syndromes" comprises somatic and psychological symptoms.

emotional basis for any unexplained physical symptom? If so, we have engaged in question begging rather than explanation.

Fortunately for scientists, health-care providers, and patients, various diagnoses and the forms of psychotherapy and pharmacotherapy applied are warranted, for the most part, by practical, empirical results. There are few cases in psychiatry in which a treatment can be shown to produce clinical benefits because it affects a well-understood mechanism that is implicated conclusively in pathogenesis. We simply do not have theories or models of mental disorders that have been validated in the manner of our theories of, for example, infectious diseases. Our technologies of healing typically are legitimized, not by the verification of the underlying theory, but by the efficacies of these technologies. Research on treatments for mental disorders is much more akin to industrial practices of "product testing" than to theory-based applied science. Fortunately for all of us, effective clinical interventions need not wait upon validated scientific theories of psychiatric disorder. We and our colleagues of today, as did the empirics of old, put our money on pragmatic, observable results of interventions, as opposed to armchair speculation about the true nature of things.

## Somatization Disorder and Subthreshold Somatization
### Overview of Diagnostic Criteria and Prevalence

Somatization disorder is the contemporary conceptualization of a syndrome that was once labeled hysteria and, more recently, Briquet's syndrome. The criteria for Briquet's syndrome were symptoms associated with a diagnosis of hystera and were incorporated into the Feighner diagnostic criteria (Feighner et al., 1972) that were the precursor to DSM-III. According to the current DSM (DSM-IV, APA, 1994), somatization disorder is characterized by a lifetime history of at least four unexplained pain complaints (e.g., in the back, chest, joints), two unexplained nonpain gastrointestinal complaints (e.g., nausea, bloating), one unexplained sexual symptom (e.g., sexual dysfunction, irregular menstruation), and one pseudoneurological symptom (e.g., seizures, paralysis, numbness). For a symptom to be counted toward the diagnosis of somatization disorder, its presence must be medically unexplained or its degree of severity be substantially in excess of the associated medical pathology. Also, each symptom must either prompt the seeking of medical care or interfere with

the patient's functioning. In addition, at least some of the somatization symptoms must have occurred prior to the patient's 30th birthday (APA, 1994). The course of somatization disorder tends to be characterized by symptoms that wax and wane, remitting only to return later and/or be replaced by new unexplained physical symptoms. Thus, somatization disorder is a chronic, polysymptomatic disorder whose requisite symptoms need not be manifested concurrently.

Epidemiological research suggests that somatization disorder is relatively rare. The prevalence of somatization disorder in the general population has been estimated to be 0.1%–0.7% (Faravelli et al., 1997; Robins & Reiger, 1991; Weissman, Myers, & Harding, 1978). When patients in primary care, specialty medical, and psychiatric settings are assessed, the rate of somatization is higher than in the general population, with estimates ranging from 1% to 5% (Altamura et al., 1998; Fabrega, Mezzich, Jacob, & Ulrich, 1988; Fink, Steen Hansen, & S ndergaard, 2005; Gureje, Simon et al., 1997; Kirmayer & Robbins, 1991; Peveler, Kilkenny, & Kinmonth, 1997).

Although somatization disorder is classified as a distinct disorder in DSM-IV, it has been argued that somatization disorder represents the extreme end of a somatization continuum (Escobar, Burnam, Karno, Forsythe, & Golding, 1987; Kroenke et al., 1997). Research suggests that the number of unexplained physical symptoms reported correlates positively with the patient's degree of emotional distress and functional impairment (Katon, Lin, Von Korff, Russo, Lipscomb, & Bush, 1991). A broadening of the somatization construct has been advocated by those wishing to underscore the many patients encumbered by unexplained symptoms that are not numerous enough to meet criteria for full somatization disorder (Escobar, Burnham et al., 1987; Katon et al., 1991; Kroenke et al., 1997).

DSM-IV includes a residual diagnostic category for subthreshold somatization cases. *Undifferentiated somatoform disorder* is a diagnosis characterized by one or more medically unexplained physical symptom(s) lasting for at least 6 months (APA, 1994). Long considered a category that is too broad because it includes patients with only one unexplained symptom, as well as those with many unexplained symptoms, undifferentiated somatoform disorder never has been well-validated or widely applied (Kroenke, Sharpe, & Sykes, 2007).

Two research teams have suggested categories for subthreshold somatization using criteria less restrictive and requiring less extensive symptomatology than the standards for DSM-IV's full somatization disorder.

Escobar and colleagues proposed the label *abridged somatization* to be applied to men experiencing four or more unexplained physical symptoms or to women experiencing six or more unexplained physical symptoms (Escobar, Burnam et al., 1987). Kroenke et al. suggested the category of *multisomatoform disorder* to describe men or women currently experiencing at least three unexplained physical symptoms and reporting a 2-year history of somatization (Kroenke et al., 1997).

Both of these subthreshold somatization categories appear to be significantly more prevalent than is *somatization disorder* as defined by DSM-IV. Abridged somatization has been observed in 4% of community samples (Escobar, Burnam et al., 1987) and 16%–22% of primary care samples (Escobar, Waitzkin, Silver, Gara, & Holman, 1998; Gureje, Simon et al., 1997; Kirmayer & Robbins, 1991). The occurrence of multisomatoform disorder has been estimated at 8% of primary care patients (Kroenke et al., 1997; Jackson & Kroenke, 2008).

### Demographic and Clinical Characteristics

The demographic characteristic most often associated with somatization is gender. In the Epidemiological Catchment Area (ECA) study, women were ten times more likely to meet criteria for somatization disorder than were men (Swartz, Landermann, George, Blazer, & Escobar, 1991). Higher rates of occurrence in women, although not as extreme, also have been found in most studies employing subthreshold somatization categories, such as Escobar's abridged somatization or Kroenke's multisomatoform disorder (Escobar, Rubio-Stipec, Canino, & Karno, 1989; Kroenke et al., 1997). A more complex picture of the association between gender and somatization was suggested by the WHO's Cross-National study, in which female primary care patients were more likely to meet criteria for full somatization disorder, but no more likely to meet Escobar's abridged somatization criteria than were their male counterparts (Gureje, Simon, et al., 1997). On the severe end of the continuum, somatization disorder is uncommon in men. Gender differences are less obvious in the various subthreshold syndromes.

Ethnicity, race, and education have been associated with somatization disorder and subthreshold somatization. Epidemiological research has shown somatization patients more likely to be female, non-white, and less educated than nonsomatizers (Gureje, Simon, et al., 1997; Robins & Reiger, 1991). Findings on ethnicity have been less consistent across studies.

In the ECA study, Hispanics were no more likely to meet criteria for somatization disorder than were non-Hispanics (Robins & Reiger, 1991). The WHO study, conducted in 14 different countries, revealed a higher incidence of both somatization, as defined by either ICD-10 or Escobar's abridged criteria, in Latin American countries than in the United States (Gureje, Simon et al., 1997).

Much attention has focused on somatization patients' illness behavior and the resulting impact of that behavior on the health-care system. These patients disproportionately use and misuse health-care services. When standard diagnostic evaluations fail to uncover organic pathology, somatization patients tend to seek additional medical procedures, often from several different physicians. Patients may even subject themselves to unnecessary hospitalizations and surgeries, which introduce the risk of iatrogenic illness (Fink, 1992). One study found that somatization disorder patients, on average, incurred nine times the U.S. per capita health-care cost (Smith et al., 1986a). Abridged somatization and multisomatoform disorder also have been associated with significant health-care utilization (Kroenke et al., 1997; Escobar, Golding, Hough, Karno, Burnam, & Wells, 1987).

The abnormal illness behavior of somatizing patients extends beyond medical offices and hospitals to patients' workplaces and households. Somatizers withdraw from both productive and pleasurable activities because of discomfort, fatigue, and/or fears of exacerbating their symptoms. In a study assessing the efficacy of cognitive behavior therapy (CBT) for somatization disorder, we found 19% of patients meeting DSM-IV criteria for somatization disorder to be receiving disability payments from either their employers or the government (Allen, Woolfolk, Escobar, Gara, & Hamer, 2006). Estimates of unemployment among somatization disorder patients range from 36% to 83% (Allen et al., 2006; Smith et al., 1986a; Yutzy et al., 1995). Whether working outside their homes or not, these patients report substantial functional impairment. Some investigators have found that somatization disorder patients report being bedridden for 2 to 7 days per month (Katon et al., 1991; Smith et al., 1986a). Likewise, high levels of functional impairment have been associated with subthreshold somatization (Allen, Gara, Escobar, Waitzkin, Cohen-Silver, 2001; Escobar, Golding, Hough, Karno, Burnam, & Wells, 1987; Gureje, Simon, et al., 1997; Jackson & Kroenke, 2008; Kroenke et al., 1997).

In addition to their physical complaints, many somatization patients complain of psychiatric distress. As many as 80% of patients meeting criteria for somatization disorder or subthreshold somatization meet DSM criteria for another lifetime Axis I disorder, usually an anxiety or mood disorder (Smith et al., 1986a; Swartz, Blazer, George, & Landerman, 1986). When investigators consider only current psychiatric diagnoses, rates of psychiatric comorbidity associated with somatization are closer to 50% (Allen et al., 2001; Simon & VonKorff, 1991). Also, overall severity of psychological distress, defined as the number of psychological symptoms reported, correlates positively with the number of functional somatic symptoms reported (Katon et al., 1991; Simon & VonKorff, 1991).

### Treatment

Several different psychosocial interventions have been used to treat somatization, some administered by mental health providers and others administered by non–mental health providers. All approaches seem to have been theoretically grounded in social learning theory. The studies are reviewed below.

Three studies have compared the efficacy of individually administered CBT with standard medical care for patients manifesting a diverse set of unexplained physical symptoms. Only one study has been published treating patients meeting DSM-IV criteria for full somatization disorder (Allen et al., 2006). Two studies were conducted in primary care settings with patients who were diagnosed with subthreshold somatization, defined as abridged somatization in one study (Escobar et al., 2007) and defined as five or more unexplained physical symptoms in the other (Sumathipala, Hewege, Hanwella, & Mann, 2000).

All three studies showed that individual CBT coincided with greater reductions in somatic complaints than did standard medical care (Allen et al., 2006; Escobar et al., 2007; Sumathipala et al., 2000). Allen et al. found that 40% of their CBT-treated participants, versus 7% of the control group, were judged to have achieved clinically significant improvement, defined as being "very much improved" or "much improved" on a clinician-rated scale of somatization severity (Allen et al., 2006). Also, CBT was associated with enhanced physical functioning in that study (Allen et al., 2006) and reduced health-care utilization in two studies (Allen et al., 2006; Sumathipala et al., 2000). Long-term maintenance of symptom relief was demonstrated in two studies; one showed significant differences in

somatization symptomatology 6 months after treatment completion (Escobar et al., 2007), and the other showed that symptom improvement lasted for 12 months after the treatment phase of the study (Allen et al., 2006).

Two groups of investigators have conducted controlled treatment trials assessing the efficacy of CBT with a less severely disturbed group of patients, those complaining of at least one "psychosomatic" symptom. In one study, patients treated with individual CBT showed greater improvement in their psychosomatic complaints than did patients treated with standard medical care (Speckens et al., 1995). The other study found group CBT, led by a trained physician, superior to a waiting-list control condition in reducing physical symptoms and hypochondriacal beliefs (Lidbeck, 1997). In both studies, improvements were observed after treatment as well as 6 months later (Lidbeck, 1997; Speckens et al., 1995). Lidbeck's CBT participants seemed to maintain reductions in somatization and hypochondriacal beliefs 18 months after treatment (Lidbeck, 2003).

Other approaches to the treatment of somatization have been focused on primary care physicians' behavior. Smith and colleagues sent a psychiatric consultation letter to patients' primary care physicians, describing somatization disorder and providing recommendations to guide primary care (Smith, Monson, & Ray, 1986b). The recommendations to physicians were straightforward: (a) to schedule somatizers' appointments every 4–6 weeks, instead of "as needed" appointments, (b) to conduct a physical examination in the organ system or body part relevant to the presenting complaint, (c) to avoid diagnostic procedures and surgeries unless clearly indicated by underlying somatic pathology, and (d) to avoid making disparaging statements, such as "your symptoms are all in your head." Patients whose primary physicians had received the consultation letter experienced better health outcomes (physical functioning and cost of medical care) than did those whose physicians had not received the letter. The results were replicated in three additional studies, one study using patients meeting criteria for full somatization disorder (Rost, Kashner, & Smith, 1994) and two studies using patients with subthreshold somatization (Dickinson, Dickinson, deGruy, Main, Candib, & Rost, 2003; Smith, Rost, & Kashner, 1995).

One other study examined the effect of group psychotherapy conducted in the primary care setting on the physical and emotional functioning of patients

meeting DSM criteria for full somatization disorder. In this study, the group treatment was developed to provide peer support, psychoeducation, and coping skills, and to encourage emotional expression. This group intervention, in combination with standard medical care augmented by the psychiatric consultation letter described earlier, was associated with significantly greater improvements in physical functioning and mental health than was the control condition—that is, standard medical treatment augmented by the psychiatric consultation letter (Kashner, Rost, Cohen, Anderson, & Smith, 1995).

Given the success of this consultation letter, the success of CBT, and the difficulties involved in distinguishing between medically explained and medically unexplained symptoms, some investigators have attempted to train primary care physicians to better detect somatization and to incorporate cognitive-behavioral techniques into their treatment of these patients. Three groups have reported controlled clinical trials on the effects of such physician training (Larisch, Schweickhardt, Wirsching, & Fritzsche, 2004; Rief, Martin, Rauh, Zech, & Bender, 2006; Rosendal et al., 2007). The one study providing the most extensive physician training (25 hours) resulted in no association between physician training and patients' symptomatology, functioning, or quality of life (Rosendal et al., 2007). Two other studies found less intensive physician training programs, 12 hours (Larisch et al., 2004) or 1 day (Rief, Martin, Rauh, Zech, & Bender, 2006) to coincide with no clear improvement in somatization symptomatology. However, Rief and colleagues did find their training to result in fewer health-care visits for the 6 months subsequent to training (Rief, Martin, Rauh, Zech, & Bender, 2006).

One additional study examined the effect of training primary care clinicians to identify and treat somatization using a biopsychosocial model (Smith et al., 2006). In this study, nurse practitioners were trained to provide a multidimensional intervention in primary care. The treatment incorporated biopsychosocial conceptualizations, behavioral recommendations, and medication management of somatization. The nurses' training program was intensive, entailing 84 hours over 10 weeks. Patients who received treatment from these trained nurses reported modest improvements on self-report scales of mental health (e.g., mood, energy) and physical functioning. A post hoc analysis was interpreted by the study's investigators as suggesting that improvements were attributable to more frequent and appropriate use of antidepressant medication among patients of nurses who received the training (Smith et al., 2006).

### Summary

The extraordinary financial costs of somatization, along with the associated suffering and disability, make it a public health concern. Initial findings on the characteristics of somatizing patients support a cognitive behavioral rationale for treatment. Six controlled clinical trials suggest that CBT may reduce physical discomfort, functional limitations, and physician visits. Additional research is required to replicate these findings. Studies designed to alter primary care treatment have had mixed results. Smith et al.'s psychiatric consultation letter, providing treatment recommendations for specific patients and labeling their symptoms as somatization, has repeatedly been shown to produce reductions in medical utilization. However, extensive training of physicians aimed at broadly affecting their approaches to working with somatization patients in their practices has had minimal effects on patient symptomatology and behavior.

## Conversion Disorder
### Overview of Diagnostic Criteria and Prevalence

Conversion symptoms (also described as pseudoneurological symptoms) are abnormalities or deficits in voluntary motor or sensory function that are medically unexplained. Some of the most common pseudoneurological symptoms are pseudoseizures, pseudoparalysis, and psychogenic movement disorders. According to DSM-IV, conversion disorder is characterized by the presence of one or more pseudoneurological symptoms that are associated with psychological stressor(s) or conflict(s) (APA, 1994). The diagnosis of conversion disorder requires a thorough psychiatric evaluation, as well as a physical examination to rule out organic neurological illness. Patients presenting with conversion symptoms typically have normal reflexes and normal muscle tone.

The course of conversion disorder appears to be different from that of somatization disorder, which tends to be chronic (Kent, Tomasson, & Coryell, 1995). The onset and course of conversion disorder often take the form of an acute episode. Symptoms may remit within a few weeks of an initial episode, and they may recur in the future. Some research indicates that a brief duration of symptoms prior to treatment is associated a better prognosis (Crimlisk et al., 1998; Hafeiz, 1980; Ron, 2001).

Estimates of the prevalence of conversion disorder have varied widely, ranging from 11/100,000 to 0.3% in the community (Faravelli et al., 1997; Stefansson, Messina, & Meyerowitz, 1979). As is the case with the other somatoform disorders, conversion disorder is much more common in medical and psychiatric practices than in community samples. As many as 25% of neurology clinic patients may present for treatment of a medically unexplained neurological symptom (Creed et al., 1990; Perkin, 1989).

### Demographic and Clinical Characteristics

The demographic characteristics of conversion disorder have not been investigated extensively. Nevertheless, there is some evidence that conversion disorder is more common among women (Deveci et al., 2007; Faravelli et al., 1997), non-whites (Stefansson, Messina, & Meyerowitz, 1979), and individuals from lower socioeconomic classes (Folks, Ford, & Regan, 1984; Stefansson, Messina, & Meyerowitz, 1979). Comorbid psychiatric distress in patients with pseudoneurological symptoms is high; it has been estimated that 30%–90% of patients seeking treatment for pseudoneurological symptoms also meet criteria for at least one other psychiatric disorder, typically somatoform disorders, affective disorders, anxiety disorders, or personality disorders (Binzer, Andersen, & Kullgren, 1997; Crimlisk et al., 1998; Mokleby et al., 2002; Sar, Akyuz, Kundakci, Kiziltan, & Dogan, 2004). A comorbid personality disorder diagnosis has been found to indicate poor prognosis of conversion disorder (Mace & Trimble, 1996).

Like somatization disorder, conversion disorder is costly to the health-care system, especially when symptoms are chronic (Mace & Trimble, 1996). Patients with longstanding conversion symptoms are likely to submit themselves to unnecessary diagnostic and medical procedures. Martin, Bell, Hermann, & Mennemeyer, (2003) report an average of $100,000 being spent per year per conversion disorder patient.

### Treatment

Conversion disorders have been treated with various approaches, including hypnosis, CBT, biofeedback, family therapy, spa treatment, pharmacotherapy, surgery, electroconvulsive therapy (ECT), physiotherapy, and inpatient psychiatric care. However, only three randomized controlled trials (RCTs) on the treatment of conversion disorder have been published: two assessing the efficacy of hypnosis (Moene, Spinhoven, Hoogduin, & van Dyck, 2002;

2003) and one assessing the efficacy of paradoxical intention therapy (Ataoglu, Ozcetin, Icmeli, & Ozbulut, 2003).

In their first study on hypnosis, Moene et al. (2002) compared the efficacy of adding hypnotherapy to an inpatient treatment for patients with motor-type conversion symptoms. All study participants were inpatients receiving a multidisciplinary treatment including group therapy, problem-solving and social skills training, exercise, physiotherapy, and bedrest. Twenty-four patients were randomly assigned to receive one hypnotherapy preparatory session and eight weekly 1-hour hypnotherapy sessions. The hypnotherapy strategies were aimed at direct symptom alleviation using suggestions designed to alter conditioned cues to motor symptoms, and emotional expression/insight involving age regression to explore factors implicated in the development of the symptoms. Also, hypnotherapy-treated participants were instructed to practice self-hypnosis for 30 minutes/day. The control comparison condition consisted of one preparatory session and eight weekly 1-hour therapy sessions "aimed at optimizing nonspecific or common therapy factors." Participants were encouraged to think and write about therapy sessions for homework. Assessments conducted 8 months after enrollment suggested that the motor symptoms of both groups had improved following baseline. However, there were no between-group differences (Moene et al., 2002).

In a second study, the same group of investigators treated outpatients diagnosed with motor-type conversion disorder. In this study, a slightly longer hypnotherapy intervention (including one preparatory session and ten weekly 1-hour sessions) was associated with better outcomes than was a waitlist control condition (Moene et al., 2003). The content of the hypnotherapy strategies and homework were the same as in their previous study (Moene et al., 2002). Experimental patients received significantly lower scores on the Video Rating Scale for Motor Symptoms and on an interviewer-based measure of physical limitations (ICIDH: International Classification of Impairments, Disabilities and Handicaps – subscale for physical activities) than did those randomized to the control waitlist condition (Moene et al., 2003). The treatment effect sizes were $d = 1.55$ for the Video Rating Scale for Motor Symptoms, and $d = 0.30$ for the ICIDH. Because these findings are based on treatment completers, not the intent-to-treat sample, they probably overestimate true differences between the treatment and control sample.

A third study compared paradoxical intention therapy provided as a part of a 3-week inpatient program with a 7-week outpatient pharmacotherapy intervention using diazepam (5–15 mg/day) combined with four outpatient medication management sessions. The paradoxical intention therapy was administered twice per day and involved asking patients to imagine anxiety-provoking situations and/or experiences. The aim was to trigger conversion attacks by helping patients reexperience putative underlying trauma (Ataoglu et al., 2003). At the end of treatment, there were no differences in the number of conversion symptoms between the groups, although the paradoxical intention group did report greater reductions in anxiety than did the diazepam group. Nevertheless, the study's findings have little validity because the differences between groups may have been attributable to other differences in treatment (i.e., inpatient versus outpatient, medication versus talk therapy) rather than to the paradoxical intention therapy itself (Ataoglu et al., 2003).

### Summary

At present, there is little evidence supporting the efficacy of any treatment for conversion disorder. The only three published randomized controlled trials contain significant methodological flaws. Before any guidelines for treatment can be formulated, there is a need for well-designed randomized controlled trials to assess the efficacy of interventions with this population.

## Pain Disorder

Pain disorder is characterized by clinically significant pain that is judged to be affected by psychological factors (APA, 1994). Very little research has been conducted that addresses pain disorder as defined by DSM-IV (or its DSM-III-R counterpart, Somatoform Pain Disorder) as a discrete diagnostic category. Instead, researchers have tended to formulate research based on the anatomical site and the chronicity of the pain. Thus, there is a voluminous literature on distinct pain conditions (e.g., back pain, chest pain, pelvic pain, headaches). In none of these studies have investigators attempted to distinguish between pain that was "affected by psychological factors" and pain that was not, presumably because such a distinction is too difficult to make. Many experts have suggested the elimination of the pain disorder category from future versions of DSM (Birket-Smith & Mortenson, 2002; Kroenke, Sharpe, & Sykes, 2007; Sullivan, 2000). Given the paucity of research on pain disorder and the uncertainty of

its future as a diagnostic category, we will not address the topic further. We have, however, addressed related conditions in the functional somatic syndrome section of this chapter (pages 347–351).

## Hypochondriasis
### Overview of Diagnostic Criteria and Prevalence

According to DSM-IV, hypochondriasis is defined as a "preoccupation with fears of having, or the idea that one has, a serious disease based on the person's misinterpretation of bodily symptoms" (APA, 1994). This preoccupation must persist despite medical evaluation and physician reassurance and cause significant distress or impairment in one's functioning (APA, 1994). Thus, unlike in somatization, where the distress and dysfunction experienced is due to the physical symptoms themselves, in hypochondriasis the distress and dysfunction is due to the patient's interpretation of the meaning of his or her symptoms. The course of hypochondriasis is often chronic; as many as 50% of patients meeting DSM criteria for hypochondriasis have excessive health concerns for many years (Barsky, Fama, Bailey, & Ahern, 1998; Barsky, Wyshak, Klerman, & Latham, 1990).

Only a few epidemiological studies have examined the prevalence of hypochondriasis. Studies that have utilized a clinical interview to assess prevalence have suggested that hypochondriasis occurs rarely in the general population. Such estimates range from 0.02% to 1.6% (Faravelli et al., 1997; Looper & Kirmayer, 2001; Martin & Jacobi, 2006). In primary care, estimates range from 0.8% to 6.3% (Barsky et al., 1990; Escobar et al., 1998; Gureje, Ustun, & Simon, 1997).

### Demographic and Clinical Characteristics

Unlike somatization disorder, hypochondriasis does not appear to be related to gender (Barsky et al., 1990; Gureje, Ustun, & Simon, 1997; Looper & Kirmayer, 2001). Men are as likely to meet DSM criteria for hypochondriasis as are women. Findings have been inconsistent on whether hypochondriasis is related to education, socioeconomic status, and ethnicity.

Like patients with somatization disorder and milder versions of somatization disorder, those with hypochondriasis exhibit abnormal illness behavior. They overutilize health care (Gureje, Ustun, & Simon, 1997; Looper & Kirmayer, 2001), subjecting themselves to multiple physician visits and multiple diagnostic procedures. They report great dissatisfaction with their medical care (Barksy, 1996;

Noyes et al., 1993). In addition, patients diagnosed with hypochondriasis report substantial physical impairment and functional limitations related to employment (Escobar et al., 1998; Gureje, Ustun, & Simon, 1997; Looper & Kirmayer, 2001; Noyes et al., 1993). Also, hypochondriasis frequently co-occurs with other Axis I disorders, such as mood, anxiety, or other somatoform disorders (Gureje, Ustun, & Simon, 1997; Noyes et al., 1994).

### Treatment

Psychosocial treatments for hypochondriasis have been examined in six randomized controlled trials. The interventions in all six studies were theoretically grounded in social learning theory and were administered on an individual basis.

The interventions labeled as cognitive therapy (CT) for hypochondriasis (Clark et al., 1998; Visser & Bouman, 2001) are procedurally similar to the point of being indistinguishable from those labeled CBT for hypochondriasis (Barsky & Ahern, 2004; Greeven et al., 2007; Warwick, Clark, Cobb, & Salkovskis, 1996). All of these interventions focused on identifying and challenging patients' misinterpretations of physical symptoms, as well as on constructing more realistic interpretations of them. Barsky and Ahern (2004) state that, in addition to restructuring cognitions, they attempted to reduce patients' tendency to amplify physical symptoms and to alter patients' illness behaviors. Warwick et al.'s CBT (1996) and Clark et al.'s CT (1998) combined cognitive restructuring with exposure to interoceptive and/or external stimuli along with response prevention after exposure. What differed most among these interventions was their duration. Barsky and Ahern's (2004) treatment entailed six 90-minute sessions. Visser and Bouman's (2001) intervention consisted of 12 weekly sessions (each presumably lasting 1 hour, although session duration was not indicated). The duration of Greeven et al.'s (2007) CBT, which was "based on Visser and Bouman's intervention," ranged from 6 to 16 sessions. Both Clark et al.'s (1998), and Warwick et al.'s (1996) treatments involved 16 one-hour sessions.

All CT and CBT interventions were associated with significantly greater reductions in hypochondriacal symptoms than was the comparable waitlist control condition (Barsky & Ahern, 2004; Clark et al., 1998; Greeven et al., 2007; Visser & Bouman, 2001; Warwick et al., 1996). Barsky and Ahern's study was the only one that examined long-term differences between the waiting list group and the treated group. Their data show that, 10 months

after treatment completion, patients enrolled in CBT reported a greater decline in hypochondriacal cognitions than did controls. Also, Barsky and Ahren's CBT-treated patients reported a significantly greater increase in daily activities than did controls, even 10 months after treatment (Barsky & Ahern, 2004).

In their study, Visser and Bouman (2001) also assessed the efficacy of a largely behavioral intervention, exposure plus response prevention. Patients receiving this treatment constructed hierarchies of their own hypochondriacal fears and avoidance behavior patterns (e.g., checking, reassurance seeking, avoidance of interoceptive and/or external stimuli). Afterward, they were given assignments of in vivo exposure and response prevention. Patients treated with exposure reported significantly greater reductions in their hypochondriacal symptoms than did waitlist control participants. Although Visser and Bouman also compared exposure plus response prevention to their CT intervention (described earlier), the study was not powered sufficiently to distinguish between the two groups.

Clark et al. (1998) created a psychosocial alternative to CT, behavioral stress management (BSM), that did not directly address hypochondriacal concerns. It was intended to address anxiety related to hypochondriasis by training patients in relaxation, problem-solving, assertiveness training, and time management. Clark et al. found behavioral stress management significantly more effective in alleviating hypochondriacal concerns than was a waiting list. Clark et al. also compared this treatment to their CT described earlier. At post-treatment CT-treated participants experienced greater reductions in their hypochondriacal cognitions than did BSM-treated participants. Nevertheless, 12 months after the post-treatment assessment, these differences were not observed (Clark et al., 1998).

Finally, Fava et al. examined the efficacy of explanatory therapy (Kellner, 1983) for hypochondriasis, in hopes of identifying a beneficial treatment that is less complex and easier to administer than CBT (Fava, Grandi, Rafanelli, Fabbri, & Cazzaro, 2000). Explanatory therapy is a physician-administered individual therapy consisting of patient education, reassurance, and training in selective attention (i.e., reducing somatic attention). Like the cognitive and behavioral treatments described earlier, explanatory therapy was found to result in greater reductions in worry about illness than was the waiting list (Fava et al., 2000). Although explanatory therapy was also associated with greater reductions in physician visits

than was the control group, the mean reduction in visits was minimal (three visits) considering that the treatment group received eight additional visits as part of their explanatory therapy (Fava et al., 2000).

The one study comparing a psychosocial intervention with a pharmacological intervention demonstrated that CBT was more effective than a placebo pill, but no more effective than paroxetine, in reducing hypochondriacal beliefs and health anxiety (Greeven et al., 2007). Despite the statistical significance of these findings, the clinical significance of changes observed in this study suggests that patients experienced only modest improvement. Instead of using Jacobson's recommendation of a change of 1.96 standard deviations from the pretreatment mean as an index of clinically significant change, the investigators judged as clinically significant a change of 1.0 standard deviation. Using this more lenient criterion, 45% of CBT recipients and 30% of paroxetine recipients versus 14% of waiting list controls responded to treatment at "clinically significant" levels (Greeven et al., 2007).

### Summary

Although the findings from controlled trials on behavioral treatment for hypochondriasis suggest that these interventions are effective in reducing hypochondriacal concerns, conclusions remain uncertain. Long-term benefits have only been assessed relative to a control condition in one study. None of the studies demonstrates that treatment has meaningful effects on measures of health-care utilization. Also inadequately examined is the impact of treatment on the functional impairment so often observed in hypochondriasis. Clinically meaningful change has not been observed. In addition, it has yet to be demonstrated that one intervention appears more potent than the others. An internal analysis of the data from a meta-analysis on psychotherapy for hypochondriasis revealed that the total amount of time with a therapist was highly correlated with the effect size as measured by standardized mean difference ($r^2 = 0.93$, $r = 0.090$ (95% CI 0.056–0.124) $p = 0.002$) (Thomson & Page, 2007).

Also noteworthy is the setting where studies on the treatment of hypochondriasis have been conducted. In each study, except that of Barsky and Ahern, patients were referred to mental health clinics by their general practitioner or mental health professional. Thus, not one of these treatments was specifically designed to be conducted in a primary care medical setting, where hypochondriasis is frequently first observed and where psychological interventions might be most advantageously applied. Because the participants in the studies described here were willing to participate in treatment in a mental health facility, they may not be representative of the majority of hypochondriacal patients who are seeking treatment for physical, not psychological symptomatology.

## Body Dysmorphic Disorder
### Overview of Diagnostic Criteria and Prevalence

Body dysmorphic disorder (BDD) is characterized by a preoccupation with an imagined defect in appearance. If a slight physical irregularity is present, the person's concern must be excessive to meet criteria for BDD. Also required for a diagnosis of BDD is significant distress or impairment caused by this preoccupation (APA, 1994). Typically, patients are concerned about their skin or complexion, the size of the nose or head, or the attractiveness of the hair. However, the preoccupation may concern any body part.

Body dysmorphic disorder tends to be chronic; in one study Phillips at al. found only a 0.09 probability of full remission and 0.2 probability of partial remission over the course of a year (Phillips, Pagano, Menard, & Stout, 2006).

The prevalence of BDD is uncertain. Research conducted in community settings has produced varying estimates: a prevalence of 0.7% in a community setting in Italy (Faravelli et al., 1997), 1.7 % in a national survey of German adolescents and adults (Rief, Buhlmann, Wilhelm, Borkenhagen, & Brähler, 2006), and 2.4% in a telephone survey of U.S. adults (Koran, Abujaoude, Large, & Serpe, 2008). The prevalence of BDD in medical practices has been found to be substantially higher than that found in the general population: 4% of general medicine patients (Phillips, 1996), 3%–16% of cosmetic surgery patients (Sarwer & Crerand, 2008), and 8%–15% of dermatology patients (Sarwer & Crerand, 2008).

### Demographic and Clinical Characteristics

Very little research has been conducted on sex and cultural differences in BDD. Phillips and Diaz found that women and men were equally likely to meet criteria for BDD (Phillips & Diaz, 1997). We are aware of no systematic investigation of race and culture in BDD, although the condition has been described in various cultures around the world (Phillips, 1996).

Patients meeting criteria for BDD have been shown to have substantial functional impairment

(Phillips, 2000). Negative thoughts about one's appearance interfere with concentration at work and the social lives of patients. In addition, individuals with BDD are so afraid of exposing their flaw to others that they go to great lengths to hide it. They may spend substantial amounts of time camouflaging their perceived defect or avoiding activities in which they will be conspicuous (Phillips, McElroy, Keck, Pope, & Hudson, 1993). Avoidance of social activities and work is common (Phillips et al., 1993).

Health-care use associated with BDD tends to be directed toward seeking various appearance-enhancing medical treatments, especially cosmetic surgery and dermatological procedures. For patients with BDD, these treatments typically fail to alleviate distress (Crerand, Phillips, Menard, & Fay, 2005; Phillips, Grant, Siniscalchi, & Albertini, 2001). Investigators have found that 48%–76% of patients with BDD sought cosmetic surgery, dermatological treatment, or dental procedures (Crerand et al., 2005; Phillips, Grant, Siniscalchi, & Albertini, 2001; Veale, Boocock, et al., 1996), and 26% received multiple procedures (Veale, Boocock, et al., 1996).

Patients meeting criteria for BDD experience an enormous amount of emotional distress and psychiatric comorbidity (Phillips, Menard, Fay, & Weisberg, 2005; Veale, Boocock, et al., 1996). Depression and suicidal thoughts are frequently reported (Gunstad & Phillips, 2003; Phillips & Menard, 2006). Also common in this population is social phobia and obsessive-compulsive disorder (Gunstad & Phillips, 2003). Often, compulsions are related to the perceived physical defect, such as checking mirrors or brushing one's hair. Many of these patients also admit to substance, particularly alcohol, use and dependence disorders (Grant, Menard, Pagano, Fay, & Phillips, 2005; Gunstad & Phillips, 2003).

Many patients preoccupied with an imagined defect in their physical appearance have such inaccurate perceptions of their appearance that they meet DSM-IV criteria for delusional disorder, somatic type. About 50% of clinical samples meeting criteria for BDD also meet criteria for delusional disorder, somatic type (Phillips, McElroy, & Keck, 1994). However, instead of considering this somatic type of delusional disorder a comorbid condition with BDD, a growing body of research suggests psychotic variants of BDD are simply a more severe form of nonpsychotic BDD and are, therefore, best conceived as on the same continuum. It seems that nonpsychotic and psychotic BDD share the same demographic characteristics, clinical characteristics, and response to treatment (Phillips, 2004). Further evidence suggests that the cognitions of BDD patients involving such matters as the degree of conviction with which these patients hold their beliefs are more indicative of a dimensional rather than a categorical structure (Phillips, 2004). Thus, the research data suggest a dimensional model of BDD with varying levels of insight indicating severity of the condition.

## Treatment

Only two randomized controlled trials have been published on the efficacy of psychosocial treatment for BDD (Rosen, Reiter, & Orosan, 1995; Veale, Gournay, et al., 1996). Both assessed the efficacy of cognitive-behavioral interventions, those involving the restructuring dysfunctional beliefs about one's body and exposure to avoided situations plus response prevention (e.g., preventing checking behavior and reassurance seeking). Whereas Rosen et al.'s treatment was administered in eight 2-hour group sessions, Veale et al. administered treatment in 12 weekly individual sessions. Both groups of investigators compared the effects of CBT with those of a waitlist control condition.

Both studies provided strong evidence for the short-term efficacy of CBT for BDD. Rosen et al. found that 81.5% of treated participants and 7.4% of control participants experienced clinically significant improvement, in that their scores on the Body Dysmorphic Disorder Examination (BDDE) dropped more than 2 standard deviations *and* they no longer met criteria for BDD. The effect size on the BDDE was substantial ($d = 2.81$) (Rosen et al., 1995). Follow-up assessment, occurring 4.5 months after treatment, was conducted with only CBT participants, 74% of whom continued to have achieved clinically meaningful gains (Rosen et al., 1995). Veale et al. reported that at post-treatment 77.8% of the treatment group either had absent or subclinical BDD symptomatology, whereas all waiting-list participants still met criteria for BDD. Furthermore, Veale's effect sizes on the BDDE and on a BDD-modified Yale-Brown Obsessive Compulsive Scale were also noteworthy ($d = 2.65$ and $d = 1.81$, respectively) (Veale, Gournay, et al., 1996). Follow-up was not investigated in this study.

Although the potency of the treatments described in these two well-designed controlled trials is noteworthy, a number of questions remain about the efficacy of CBT for BDD. No additional RTCs have been published. Cognitive-behavioral therapy has not been compared with alternative treatments nor with an attention control. It is unclear whether the treatment gains reported here could be attributable

to nonspecific aspects of therapy. Also, long-term follow-up has not been adequately studied. Other important outcomes, such as physical and social functioning and health-care use, have not been assessed. Finally, the generalizability of these findings is unclear. Between the two studies, only 36 patients have been treated. Rosen et al.'s sample consisted of women, 83% of whom had body weight and shape concerns. Veale et al.'s sample specifically excluded potential participants with body weight and shape concerns.

## Related Conditions: Functional Somatic Syndromes
### Overview of Diagnostic Criteria and Prevalence

The term *functional somatic syndrome* is used to describe groups of co-occurring symptoms that are medically unexplained. Each area of medicine identifies at least one functional somatic syndrome for patients who present with symptoms that are common in that area of medicine, but have uncertain pathology and a poor prognosis. Three polysymptomatic functional somatic syndromes frequently encountered by both mental health and primary care practitioners are irritable bowel syndrome (IBS), chronic fatigue syndrome (CFS), and fibromyalgia. As will be discussed here, they all share many of the characteristics of the somatoform disorders.

*Irritable bowel syndrome* is characterized by persistent abdominal pain along with altered bowel habits and abdominal distension that cannot be explained by organic pathology (Thompson, Dotevall, Drossman, Heaton, & Kruis, 1989). It has been estimated that 8%–20% of the U.S. population, 12% of primary care patients (Drossman, Whitehead, & Camilleri, 1997), and 22%–28% of gastroenterologists' patients are afflicted with IBS (Harvey, Salih, & Read, 1983; Thompson & Heaton, 1980).

*Chronic fatigue syndrome* is characterized by unexplained fatigue, lasting at least 6 months, that causes substantial reductions in activities. At least four of the following symptoms must have co-occurred with the fatigue: significant memory impairment or concentration difficulties, sore throat, tender lymph nodes, muscle pain, joint pain, headache, nonrestorative sleep, and postexertional fatigue (Fukuda et al., 1994). The prevalence of CFS has been estimated to be 0.002%–0.6% in the general population and 2.6% in primary care settings (Jason et al., 1999; Reyes et al., 2003; Wessely, Chadler, Hirsch, Wallace, & Wright, 1997).

A diagnosis of *fibromyalgia* is given for chronic widespread pain and multiple tender points that have no known biological basis and are accompanied by nonrestorative sleep, fatigue, and malaise (Wolfe et al., 1990). Fibromyalgia has been estimated to occur in about 2% of the U.S. population and in 6%–20% of general medical outpatients (Wolfe, Ross, Anderson, Russell, & Hebert, 1995).

### Demographic and Clinical Characteristics

Women are more likely than men to suffer from all three syndromes: IBS (Drossman et al., 1993), CFS (Jason et al., 1999; Reyes et al., 2003), and fibromyalgia (Wolfe et al., 1995). Although the incidence of CFS and fibromyalgia have been shown to be elevated in minority groups in the United States, larger epidemiological studies are required to confirm these findings (Gansky & Plesh, 2007; Jason et al., 1999).

Our decision to include the research on CFS, fibromyalgia, and IBS in this chapter on somatoform disorders may invite controversy. Some medical specialists, focusing upon the bodily organ or somatic system of their specialization, assume these disorders have distinct pathophysiological causes and draw sharp distinctions among these syndromes. Other authorities suggest these syndromes should be viewed as one disorder. After all, many patients diagnosed with one functional somatic syndrome meet diagnostic criteria for one or more of the other functional somatic syndromes, resulting in multisystem comorbid functional syndromes (Buchwald & Garrity, 1994; Goldenberg, Simms, Geiger, & Komaroff, 1990; Veale, Kavanagh, Fielding, & Fitzgerald, 1991; Yunus, Masi, & Aldag, 1989). Also, investigators have noted similarities in the illness behaviors, illness beliefs, and psychological functioning of patients diagnosed with one of these functional somatic syndromes and those diagnosed with a somatoform disorder (Barsky & Borus, 1999; Rief, Hiller, & Margraf, 1998; Wessely, Nimnuan, & Sharpe, 1999). As discussed earlier regarding patients with somatoform disorders, patients with functional somatic syndromes tend to adopt a sick role (Parsons, 1951), overutilizing medical services and withdrawing from their normal activities. They tend to assume their symptoms are signs of a serious, disabling illness that is likely to worsen; they think "catastrophically" about their health. They frequently suffer from concurrent emotional disorders (see Woolfolk & Allen, 2007, for further review).

### Treatment

Various psychosocial interventions have been used to treat the functional somatic syndromes. Short-term dynamic therapy, relaxation training, exercise

regimens, behavior therapy, cognitive therapy, and CBT have been tested in controlled studies with one or more of the patient groups described. The studies are reviewed here. A more detailed examination of this literature can be found elsewhere (Allen, Escobar, Lehrer, Gara, & Woolfolk, 2002).

## SHORT-TERM DYNAMIC THERAPY

Psychodynamic theory has proposed that unexplained physical symptoms are produced to protect the patient from traumatic, frightening, and/or depressing emotional experiences. If an individual fails to process a trauma adequately, it is hypothesized, the original affect later may be converted into physical symptoms (Engel, 1959). Short-term dynamically oriented treatments that explore the stress and emotional distress associated with physical symptoms have been studied systematically with IBS patients. In one study, a short-term dynamic therapy, aimed at "modifying maladaptive behaviour and finding new solutions to problems," resulted in significantly greater improvement in IBS symptoms than did a standard medical care condition. Differences between groups were observed after treatment as well as 1 year later (Svedlund, Sjodin, Ottosson, & Dotevall, 1983). Another trial examined the efficacy of a short-term dynamic therapy aimed at helping participants explore the links between IBS symptoms and emotional factors. The treatment was supplemented by audiotape-administered relaxation methods that participants were instructed to use at home. Immediately after the 3-month intervention phase, participants receiving psychotherapy reported significantly greater improvements in IBS symptoms than did participants receiving standard medical care (Guthrie, Creed, Dawson, & Tomenson, 1991). This second intervention (psychodynamic therapy plus relaxation training) was more recently compared to pharmacotherapy with paroxetine and to standard medical care for IBS. Although there were no differences among the three treatment conditions in patient-reported abdominal pain, both dynamic therapy and paroxetine coincided with greater improvement in physical functioning than did standard medical care a year after treatment. Furthermore, psychotherapy, but not paroxetine, was associated with greater reductions in health-care costs during the year after treatment (Creed et al., 2003).

## RELAXATION TRAINING

Psychophysiologists have described several mechanisms that produce somatic symptoms in the absence of organic pathology (Clauw, 1995; Gardner & Bass, 1989). These mechanisms include overactivity or dysregulation of the autonomic nervous system, smooth muscle contractions, endocrine overactivity, and hyperventilation. Miscellaneous techniques, directed at reducing physiological arousal and physical discomfort associated with unexplained physical symptoms, have been studied within controlled experimental designs. Small studies have shown that relaxation techniques, such as electromyogram (EMG)-biofeedback and guided imagery, reduce pain associated with fibromyalgia more effectively than do sham relaxation treatments (Ferraccioli et al., 1987; Fors, Sexton, & Gotestam, 2002). In another small trial, patients treated with progressive muscle relaxation reported greater relief in their irritable bowel symptoms than did patients in a control comparison treatment condition (Blanchard, Greene, Scharff, & Schwarz-McMorris, 1993).

Hypnotherapy, designed to produce generalized relaxation and control of intestinal motility, has been successfully applied to IBS as well as to fibromyalgia. In three different studies, hypnotherapy was associated with less abdominal pain and fewer abnormal bowel habits than was either of two comparison conditions, supportive psychotherapy combined with a placebo pill (Whorwell, Prior, & Farragher, 1984) or a symptom-monitoring condition (Galovski & Blanchard, 1998; Palsson, Turner, Johnson, Burnett, & Whitehead, 2002). The one study assessing the efficacy of hypnotherapy for fibromyalgia found it to be associated with greater pain relief than was physical therapy (Haanen et al., 1991). In an attempt to examine the mechanism of improvement, Palsson et al. showed that improvements seen in IBS symptoms after hypnotherapy were related to improvements in somatization and in anxiety, but not related to physiological measures of rectal pain threshold, rectal smooth muscle tone, or autonomic functioning (Palsson et al., 2002).

## EXERCISE TREATMENTS

Exercise interventions have been developed for CFS and fibromyalgia, in accordance with evidence suggesting that exercise improves mood, pain thresholds, and sleep (Minor, 1991; Weyerer & Kupfer, 1994). One theory explaining the benefits of exercise proposes that exercise produces increases in serum levels of β-endorphin-like immunoreactivity, adrenocorticotropic hormone, prolactin, and growth hormone (Harber & Sutton, 1984). In most studies, graded exercise treatments have coincided with

improvements in physical functioning, fatigue, and global perceived well-being in patients diagnosed with CFS or fibromyalgia (Fulcher & White, 1997; Martin et al., 1996; McCain, Bell, Mai, & Halliday, 1988; Powell, Bentall, Nye, & Edwards, 2001; Richards & Scott, 2002). Some trials have even shown exercise to outperform relaxation and/or stretching comparison interventions (Fulcher & White, 1997; Martin et al., 1996; McCain, Bell, Mai, & Halliday, 1988; Richards & Scott, 2002). Although both statistically and clinically significant gains have been reported, the findings reported here probably are not generalizable to all CFS and fibromyalgia patients. First, some investigators have not found an association between exercise treatments and symptom relief (King, Wessel, Bhambhani, Sholter, & Maksymowych, 2002; Mengshoel, Komnaes, & Forre, 1992). Second, many patients are disinclined to exercise and, thus, are unlikely to enroll in exercise studies. Finally, some studies have produced high attrition rates (Martin et al., 1996; Wearden et al., 1998) indicating that even those patients who agree to undergo an exercise regimen may not adhere to it.

### BEHAVIOR THERAPY

Operant behavior therapy manipulates the consequences of patients' illness behavior with the aim of alleviating the associated pain and impairment. Recipients of operant behavior therapy are rewarded as they display "healthy behaviors" and increased activity levels; additional activities are expected to result in positive interactions with the outside world, experiences of joy, and a sense of productivity. Pain behaviors, such as taking medication, wincing, complaining, and seeking treatment, are identified, labeled, and consequated. A recent study compared the efficacy of an inpatient, operant behavioral treatment to that of inpatient physical therapy for fibromyalgia (Thieme, Gromnica-Ihle, & Flor, 2003). Operant behavior therapy was conducted in groups of five to seven patients for 5 weeks. Immediately after treatment, as well as 6 and 15 months after treatment, behavior therapy was associated with substantial reductions in pain intensity, use of medication, and physician visits (Thieme et al., 2003). The only other randomized controlled study of behavior therapy for a functional somatic syndrome was conducted with outpatients diagnosed with IBS. In this study, patients who received six to 15 sessions of individual behavior therapy reported no more improvement than did control participants (Corney, Stanton, Newell, Clare, & Fairclough, 1991).

Discrepancies in findings from these two studies may be related to differences in patient populations (fibromyalgia vs. IBS; inpatient vs. outpatient) or the mode of administration of the intervention (group vs. individual). Additional research on the efficacy of behavior therapy for functional somatic syndromes is required before such interventions can be endorsed.

### COGNITIVE THERAPY

Cognitive therapy focuses on and attempts to alter faulty thinking patterns associated with functional somatic symptoms. Three trials with IBS patients have shown individual cognitive therapy to be associated with greater reductions in IBS symptoms than were either a waiting-list control condition or a support group (Greene & Blanchard, 1994; Payne & Blanchard, 1994; Vollmer & Blanchard, 1998).

### COGNITIVE-BEHAVIORAL THERAPY

Cognitive-behavioral therapy aims to alter dysfunctional thoughts and behaviors associated with somatic symptoms. With IBS patients, CBT usually has included a relaxation component. Controlled trials of CBT interventions for IBS have produced inconsistent results. Five trials showed CBT, administered individually, relieved bowel symptoms more effectively than did standard medical care (Heymann-Monnikes et al., 2000; Shaw et al., 1991), an educational attention-control condition (Drossman et al., 2003), or a waiting list (Lynch & Zamble, 1989; Neff & Blanchard, 1987). In a sixth study, CBT administered as a group treatment resulted in greater improvements in IBS symptoms than did a waiting list control condition (Van Dulmen, Fennis, & Bleijenberg, 1996). Four other investigations found no difference between individual CBT and a control condition (Bennett & Wilkinson, 1985; Blanchard, Schwarz, Suls, Gerardi, & Scharff, 1992a; Blanchard, Schwarz, Suls, Gerardi, & Scharff, 1992b; Boyce, Talley, Balaam, Koloski, & Truman, 2003).

Studies of CBT for IBS have not yielded a consistent pattern of results. Discrepancies in the findings of the earliest studies were to be expected, given their lack of methodological rigor. Findings that have emerged from the two most recently published and methodologically sound studies on CBT for IBS also are not congruent (Boyce et al., 2003; Drossman et al., 2003). Identifiable differences between the more recent studies' designs and outcome measures potentially provide some insight into the discrepancies in findings. Whereas Drossman et al. found

CBT more effective than an educational intervention, Boyce et al. found CBT no more effective than an 8-week relaxation treatment (Boyce et al., 2003; Drossman et al., 2003). Because Boyce's comparison treatment condition, a relaxation intervention, has been demonstrated in past studies to reduce IBS symptoms (Blanchard et al., 1993), it was likely to have been more "active" than was Drossman al.'s control condition. Drossman et al.'s primary outcome measure was a composite of the following variables: satisfaction with treatment, global well-being, diary abdominal pain scores, and health-related quality of life (Drossman et al., 2003). Boyce et al., on the other hand, measured outcome with the Bowel Symptom Severity Scale, a measure of frequency, disability, and distress caused by each of eight gastrointestinal symptoms. Treatment satisfaction and global well-being were not assessed in the Boyce et al. study (2003). The results of these two studies suggest that CBT may help patients with IBS cope with their symptoms and with their lives better than would educational sessions, but may not relieve specific IBS symptoms any better than would relaxation treatments.

When CBT has been administered to CFS patients, it has not included relaxation training. Instead, encouragement to increase activities, including exercise, has been a key component of these interventions. In one study, CBT was no more effective than the control treatment (Lloyd et al., 1993), whereas in three other studies CBT reduced fatigue significantly more than did relaxation (Deale, Chalder, Marks, & Wessely, 1997), support groups (Prins et al., 2001), or standard medical care (Sharpe et al., 1996). One study found the superiority of CBT over relaxation to be maintained for 5 years after treatment (Deale, Kaneez, Chalder, & Wessely, 2001). The trials that found CBT to be efficacious employed more intensive treatments than did the one unsuccessful trial. The clinical impact achieved in the successful trials, coupled with the methodological quality of the trials, lends further support to the use of CBT with CFS patients.

For fibromyalgia, the efficacy of *group CBT*, but not of *individually administered CBT*, has been studied in controlled trials with fibromyalgia patients. Patients treated with a six-session group CBT reported significantly more improvement in physical functioning, but not in pain, 12 months after baseline when compared with patients who had received standard medical care (Williams et al., 2002). Another trial, comparing the efficacy of a group CBT to that of group relaxation training (autogenic training), showed no differences between the conditions at post-treatment. However, 4 months later, CBT participants reported a greater reduction in pain intensity than did the autogenic training participants (Keel, Bodoky, Gerhard, & Muller, 1998). Two trials comparing a CBT/education group with a discussion/education group found no differences in pain complaints or functioning between the two treatment conditions (Nicassio et al., 1997; Vlaeyen et al., 1996). The findings of a less-than-powerful impact of CBT on fibromyalgia may reflect the ineffectiveness of group-administered treatment for this population. The benefits of individual CBT have yet to be explored with fibromyalgia patients.

## SUMMARY

As a whole, psychosocial interventions have been moderately effective in reducing the physical symptoms associated with functional somatic syndromes. Investigators who reported long-term outcome data suggest that benefits persist as much as a year after treatment. Although detailed descriptions of most interventions are not provided in research articles, close scrutiny of the studies' methods sections suggests a great deal of overlap among the interventions. For example, one of the dynamically oriented therapies included a relaxation component. The other dynamic treatment involved directive interventions: encouraging patients to change maladaptive behavior and to engage in problem-solving exercises. Cognitive-behavioral training often incorporated relaxation training or homework assignments directing patients to engage in physical exercise. With so much overlap among treatments, perhaps it is not surprising that none of the interventions appears to be more potent than any of the others.

## PSYCHOSOCIAL VERSUS PHARMACOLOGICAL TREATMENTS

A few studies have compared the efficacy of a psychosocial intervention with a pharmacological treatment for functional somatic syndromes. Chronic fatigue syndrome patients who participated in an exercise treatment reported greater improvements in fatigue and functional capacity than did CFS patients treated with fluoxetine (Wearden et al., 1998). Guided imagery produced superior results in fibromyalgia pain than did amitriptyline (Fors, Sexton, & Gotestam, 2002). And, Svedlund et al.'s (1983) psychodynamic treatment outperformed the control treatment, which included physician-prescribed bulking agents, anticholinergic drugs,

antacids, and minor tranquilizers. These last two studies, those of Fors et al. and Svedlund et al., suggest a psychosocial intervention might be more effective than the medications most frequently prescribed for fibromyalgia and IBS, respectively. Nevertheless, too few studies have made the kinds of comparisons that would allow this conclusion to be asserted with certitude. Additional research is needed to examine the relative efficacy, and also the combined efficacy, of pharmacological and behavioral interventions with functional somatic syndromes and with somatoform disorders.

## Factitious Disorder
### Overview of Diagnostic Criteria and Prevalence
A diagnosis of factitious disorder is made when a patient intentionally produces, feigns, or exaggerates physical or psychological symptoms in order to assume the sick role. Identifiable external incentives, as would be the case when a person malingers for a specific purpose, are not present in factitious disorder (APA, 1994). Patients meeting DSM-IV criteria for factitious disorder with predominantly physical signs and symptoms are represented in most fields of medicine. Symptoms may be fabricated (e.g., claiming blindness when vision is unimpaired), intentionally produced (e.g., hematuria when patient intentionally pricks a finger to add blood to his or her urine), or exaggerated (e.g., exaggerations of pain). In factitious disorder with predominantly psychological signs or symptoms, patients may feign, exaggerate, or intentionally produce (e.g., such as with psychoactive substances) psychiatric symptoms, often psychosis.

The prevalence of factitious disorder has not been systematically investigated. Verification of the diagnosis is particularly difficult. Not only do organic explanations have to be excluded, but also the patient's role in and motivation for creating the symptom has to be determined. Physicians may be reluctant to consider factitious disorder as a potential differential diagnosis (Krahn, Li, & O'Connor, 2003). One study surveying physicians in internal medicine, neurology, dermatology, and surgery for their estimates of the prevalence of factitious disorder with predominantly physical symptoms in their practices found a range of from 0.0001% to 15%, with an average of 1.3% (Fliege et al., 2007).

### Demographic and Clinical Characteristics
The scientific literature on factitious disorder consists of only case studies and clinical record reviews. At present, the demographic and clinical characteristics of factitious disorder are unknown.

### Treatment
Treatment approaches for factitious disorder also have not been investigated systematically. Some clinicians have suggested that treatment should include confrontation of the patient (van der Feltz-Cornelis, 2002), whereas others recommend supportive, nonconfrontational treatment (Eisendrath, Rand, & Feldman, 1996). Many patients discontinue treatment when confronted directly with the diagnosis (Krahn et al., 2003). At present, we have no evidence to guide our treatment of factitious disorders.

## Conclusion
An evaluation of the empirical research on psychosocial treatments for somatoform and related disorders suggests that, in some respects, it mirrors the literature on evaluating the efficacy of psychotherapy with generic mental disorders. A number of different focused psychosocial treatments have been shown to be superior to various control conditions, especially waiting lists or standard medical treatment. Effect sizes are respectable, relative to other medical or quasi-medical interventions. There is little evidence that one form of treatment is superior to any other. Treatments that are appropriately conceived as forms of CBT are the most frequently studied, have a creditable record of success, and, by the sheer volume of data, would appear to be the best candidates for a designation of "empirically supported" treatments.

Although the literature on the specific somatoform and factitious disorders is relatively small, a few global conclusions can be posited. Cognitive-behavioral therapy for somatization, hypochondriasis, IBS, and CFS is moderately effective, probably with some lasting effects. However, there is little data on the impact of treatment on health-care utilization, especially when the cost of a psychosocial intervention, such as those described earlier, is factored into the equation. There is inadequate data on the treatment of conversion disorder, pain disorder, or factitious disorder to make any conclusion. The data on CBT's efficacy on BDD is the most powerful. Effect sizes are large, and the vast majority of patients appear to have made clinically meaningful gains from treatment. However, the two groups of investigators who have systematically studied CBT's efficacy in BDD acknowledge residual symptoms persist and argue for a longer, more intensive

treatment before these patients are likely to resolve their difficulties. Longer-term treatments for other somatoform disorders have been recommended by others as well (Woolfolk & Allen, 2007).

We have very little data on the mechanisms by which efficacious psychosocial treatments may have their impact upon somatoform disorders. There are multiple reasons for this. First, the "mediators and moderators" style of research has not been extensively applied to research on somatization. Second, the treatments studied have not been disassembled into discrete components and those constituents systematically assessed. Evidence that might shed some light on this issue, pertaining to differential efficacy of treatment, is also scant. This absence of evidence, to some extent, is the result of much overlap among treatments. Even treatments with very different labels (e.g., brief psychodynamic therapy and CBT) turn out to be similar procedurally—for example, both identifying stressors and providing training in relaxation. When reading the somatoform treatment literature, careful attention must be paid to methods sections, as the labeling of treatments can often be somewhat misleading.

Somatoform researchers as a whole recommend treatment for these conditions be administered in primary care settings. It has been estimated that 50%–80% of patients with somatoform disorders who are referred for mental health services fail to seek mental health treatment (Escobar, Waitzkin, Silver, Gara & Holman, 1998; Regier et al., 1988). Barriers to following through with psychiatric referrals occur at both the systemic level (e.g., lack of collaboration between and proximity of primary care physicians and mental health practitioners, lack of mental health training for primary care physicians, inadequate mental health insurance) and individual level (e.g., concerns about the stigma of having a psychiatric disorder, resistance to psychiatric diagnosis, health beliefs that lead to somatic presentations, pessimism, and fatigue) (Pincus, 2003). The efficacy of CBT conducted in primary care has not been studied adequately for hypochondriasis or BDD.

The treatment of somatoform and factitious disorders via psychosocial methods is very much in its infancy. The methodological quality of the early research has been uneven. Nevertheless, there is sufficient evidence to believe that psychosocial interventions have therapeutic value for a number of these disorders. For somatization, hypochondriasis, BDD, and many of the functional somatic syndromes, CBT is likely the treatment of choice by default, in that no other intervention has demonstrated efficacy.

# Trauma, Dissociation, and Post-traumatic Stress Disorder

Terence M. Keane, Brian P. Marx, Denise M. Sloan, *and* Anne DePrince

## Abstract

Worldwide, post-traumatic stress disorder (PTSD) is among the most common psychological disorders; over the past three decades researchers have made considerable progress in understanding the prevalence of PTSD and its psychological and biological underpinnings, while developing methods for its assessment and treatment. Only included in the diagnostic nomenclature since 1980, the history of PTSD extends as far back as the oldest literature in Western civilization. Homer's *Iliad* and *Odyssey* capture the impact of war on combatants and civilians, as do many of the works of writers and artists across the centuries. The focus of this chapter is on the integration of contemporary work on traumatic stress exposure, psychological dissociation, and the development of PTSD, a disorder characterized by concurrent high levels of anxiety and depression and, in many instances, considerable chronicity and disability. More than 50 randomized controlled treatment outcome studies suggest that cognitive-behavioral treatments are especially effective, and support the use of exposure therapy, stress management therapy, cognitive therapy, cognitive processing therapy, and eye movement desensitization and reprocessing in treating PTSD. All these approaches constitute key evidence-based psychological treatments for PTSD. Future work will determine which treatments used by which therapists are best for patients with specific symptoms and concomitant conditions.

**Key Words:** Dissociation, post-traumatic stress disorder, stress, trauma

The earliest cultural works of Western civilization describe the devastating personal impact of exposure to violence, war, and related trauma. The psychological consequences of these experiences are well captured in the art, literature, and theatrical plays that describe the human condition throughout the centuries. Eloquent descriptions of trauma sequelae can be found in reference to the Civil War (e.g., Stephen Crane's description in *The Red Badge of Courage*), the presence of "irritable heart" among soldiers (Da Costa, 1871), Page's (1883) conception of railroad spine (distress following train crashes in the United Kingdom), the psychological consequences of the disastrous 1666 Great Fire of London (Daly, 1983), and even the Trojan War (e.g., the story of Ulysses in Homer's *Iliad*). Anxiety as a specific

response to severe or traumatic life stress is described by Oppenheim (1892; cited by Kraepelin, 1896), who labeled this response as "traumatic neurosis," and by Kraepelin (1896) who labeled it "Schreckneurose" (i.e., fright neurosis). Each of these early contributors to diagnostic nomenclature recognized something special and perhaps distinct about the psychological disorders that emerge from exposure to traumatic life events.

Despite these common observations throughout history, the scientific study of traumatic responses is a recent enterprise. After World Wars I and II, studies of psychological distress among combatants and concentration camp survivors set the stage for the recognition of the long-term negative effects of trauma exposure. Terms such as "shell shock," "combat fatigue,"

and "war neurosis" all seemed to capture the essence of war-related post-traumatic stress disorder (PTSD), but the psychological effects of other traumatic life stressors were not recognized in the research literature until Ann Burgess at the famed Boston City Hospital observed the impact of rape on women (Burgess & Holmstrom, 1974). Once advocates for rape survivors and Vietnam veterans teamed with scholars who had studied and treated World War II veterans and concentration camp survivors, the diagnosis of PTSD emerged in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM) of the American Psychiatric Association (APA, 1980).

Given the consistent historical precedence associated with the notion of a trauma condition, it is somewhat surprising that controversy regarding its validity emerged during the 1970s and '80s (Figley, 1978; Goodwin & Guze, 1984). Although much of the initial controversy about PTSD's validity has ceased, the nature of the disorder still instigates considerable debate in the field (see Brewin, 2003; Weathers & Keane, 2007). Conceptual issues still exist about the precise definition of PTSD, about which symptoms should define the disorder, and the proposition that PTSD is simply a social construction, not a psychiatric disorder (McNally, 2004).

*Dissociation* is a more modern term that developed from the 19th-century origins of contemporary psychiatry. Pierre Janet, of the Salpetriere in Paris, discussed the cognitive and behavioral consequences of exposure to traumatic events. He described many of the basic phenomena that we now characterize as dissociative through his interviews with patients who were then viewed as suffering from hysteria. Alterations in consciousness, observed defects in attention and memory, and suggestibility are key components of dissociation. Theories of psychopathology proposed by the Europeans Charcot (1887), Janet (1909), and Freud (1896) all relied upon the storage of emotionally laden material in an altered level of consciousness (dissociated state) that adversely influenced the individual's behavior, cognition, and affect. This stored material affected one's view of the world, the way one interacted with the world, and the emotional state in which one lived.

More recent views of dissociation directly connect dissociative states to the field of psychological trauma and PTSD. Although some authorities state that traumatic events spawn the development of dissociative experiences as a direct function of the overwhelming emotions associated with the event (van der Kolk & Fisler, 1995), others propose that dissociation at the time of the event (peritraumatic

dissociation) is a potent biopsychological phenomenon that is an important etiological variable in the ultimate development of PTSD (Marmar et al., 1994; Ozer, Best, Lipsey, & Weiss, 2003). In the former conceptualization, the stress is so extreme that a protective splitting from reality into fantasy mitigates the impact of the event. In the latter formulation, dissociation at the time of the event appears to function as a protective mechanism immediately, but ultimately results in the development of the very disabling condition we know as PTSD. These findings suggest that dissociation is a cognitive mechanism that precludes the adaptive processing of the emotional concomitants of the traumatic experience.

Freyd (1996) and her colleagues (DePrince & Freyd, 1999; 2004; Freyd, Klest, & Allard, 2005) studied what might amount to the most challenging area of research in the field of trauma: failure to recall highly significant traumatic life events such as childhood sexual abuse or even combat events. In 1994, Linda Williams reported on a cohort of women who were sexually abused as children, and learned that a high percentage of these women didn't recall the index episode of sexual abuse. This study, and observations by clinicians nationwide, instigated an intense debate about whether it is possible for people to forget the memories associated with such a significant life event. Freyd's premise, termed "Betrayal Trauma Theory" relied upon Darwinian survival notions to help us understand why children exposed to incest or violence in the home might not recall such experiences. The greater the reliance upon responsible caretakers and the closer the abuser is to the abused, the less likely the individual is to bring this abuse into consciousness. This betrayal by a needed caretaker results in motivation for the abused to not recall the events by the abuser. To do so might threaten the abused person's very survival. Freyd's work established a scientific foundation for understanding the cognitive and motivational aspects of one form of dissociative experience: the absence of recall of significant aspects of a traumatic event.

In its current conception of psychological trauma, the DSM-IV (American Psychiatric Association [APA], 1994) defines PTSD as necessarily stemming from an event in which one is exposed to serious threat of injury or death and then experiences extreme fear, helplessness, or horror. Three symptom clusters define the disorder. In addition to recurrent and intrusive recollections and dreams of the event, the "reexperiencing" cluster includes the experience of "flashback" episodes wherein an individual experiences a recurrence of at least a portion of the trauma.

"Hyperarousal" symptoms are characterized by an enhanced startle reaction and difficulty sleeping, concentrating, and controlling anger, as well as hypervigilance for danger and a sense of a foreshortened future. Extreme distress and avoidance of cues or reminders of the trauma, as well as an inability to remember aspects of the event, also can accompany this disorder. Additional "avoidance" symptoms include emotional numbing, described as an inability to feel any positive emotions such as love, contentment, satisfaction, or happiness.

The interpersonal, psychosocial, physical health, and societal consequences of PTSD are considerable. Those with PTSD are more likely to divorce, report trouble raising their children, engage in intimate partner aggression, experience depression and other psychological problems, report poorer life satisfaction and physical health problems, become involved with the legal system, earn less, and change jobs frequently (Jordan et al., 1992; Koss, Woodruff, & Koss, 1991; Kulka et al. 1990; Schnurr & Green, 2004; Walker et al., 2003). These findings suggest that PTSD constitutes a major problem for the public health of this nation and the world, and highlight the importance of prevention and intervention efforts. As with many conditions, to date we've accomplished more in terms of treatment than in prevention, although progress in this domain is beginning to emerge in the literature and especially with respect to the military (Adler, Bliese, McGurk, Hoge, & Castro, 2009). The purpose of this chapter is to highlight the interrelationships among trauma exposure, dissociative phenomena, and the development of PTSD and related psychological conditions. In it, we will highlight progress in both the assessment and treatment of PTSD, as well as provide an understanding the prevalence of this disorder.

## Trauma Spectrum

In multiple venues, we have proposed the creation of a category of *trauma spectrum disorders* (Keane, 2008; Keane & Miller, 2009) as a result of new evidence that PTSD and its related conditions don't appear to fit with other anxiety disorders. In addition, it was our premise that, conceptually, it is more appropriate for disorders that occur in proximity to exposure to an extreme life event are best classified together. For our purposes, we considered clustering together the following psychological conditions: PTSD, acute stress disorder (ASD), adjustment disorder, dissociative disorders, trauma-related phobias, grief, bereavement, and trauma-related personality disorders.

Our thinking on this issue is related to several converging sources of information. First, it is clear that anxiety or fear is only one aversive emotion that can lead to PTSD. Other intense emotional experiences can lead to PTSD, such as rage, horror, guilt, and shame. Second, PTSD is only one of several possible outcomes of exposure to a traumatic event. Other Axis I and Axis II conditions can emerge: depression, phobias, substance abuse, and personality disorders are common.

Third, those disorders that are conditional on exposure to a precipitating traumatic event seem logically to share common elements. For example, PTSD, ASD, adjustment disorder, pathological grief, and bereavement all share a proximal instigating event and attendant emotional responses, whether these were fear, loss, or shame. Fourth, PTSD doesn't appear to aggregate with other items in the anxiety disorders. For example, Slade and Watson (2006) found that in the structure of common mental disorders, PTSD was more strongly associated with major depression, dysthymia, and generalized anxiety disorder rather than with the other key anxiety disorders like panic, social phobia, agoraphobia, and obsessive-compulsive disorder all of which were more highly correlated with one another. Similarly, Miller, Fogler, Wolf, Kaloupek, and Keane (2008) found that PTSD in combat veterans was more strongly related to major depression and alcohol abuse than it was to panic disorder, agoraphobia, and obsessive-compulsive disorder. Thus, trauma-related psychopathology shares more in common with other conditions than it does with the anxiety disorders.

Fifth, we feel that the causal influence of PTSD on the high rates of comorbidity often observed in people with PTSD (cf., Keane & Wolfe, 1990) are important new findings in this literature. For example, PTSD typically leads to depression or substance abuse, but the inverse relationship doesn't appear to be as strong. Breslau, Davis, Peterson, and Schultz (2000) first demonstrated this in their longitudinal cohort of young adults in the Detroit metropolitan area. In a related series of analyses, Brown, Campbell, Lehman, Grisham, and Mancill (2001) found that when they examined the onset of comorbid depression, obsessive-compulsive disorder, panic disorder, alcohol abuse, and drug abuse in cases of PTSD, these disorders were far more likely to develop once PTSD was present. This causal influence of PTSD on comorbid psychopathology suggests a distinct phenomenology that should be reflected in its diagnostic class membership within the DSM. Constructing a spectrum of trauma-induced disorders appears to

be one viable solution for the most appropriate placement of PTSD and related conditions.

Finally, Miller, Resick, and Keane (2008) reviewed studies of adult psychopathology that assert that childhood and/or adolescent anxiety disorders foreshadow the emergence of adult anxiety problems. Post-traumatic stress disorder departs from the other anxiety disorders in this realm too; adults with PTSD often display externalizing disorders as children (rather than the more typical internalizing precedents in anxiety disorders; Gregory et al., 2007). This represents more evidence that PTSD may actually be better situated with other disorders of stress exposure rather than with anxiety.

## Further DSM Considerations

Irrespective of the placement of PTSD in the DSM, the diagnostic criteria for PTSD need modification. Weathers and Keane (2007) reviewed the literature with respect to the bifurcation of Criterion A into A1 – trauma event exposure, and A2 – trauma event response. We found that this exposure–response distinction did very little to tighten the entrance into the diagnosis, as was initially intended. As a result, most authorities are recommending the combining of A1 and A2 into a single dimension of exposure.

Other issues pertain to the existing criteria. In particular, confirmatory factor analytic studies (e.g., King, Leskin, King, & Weathers, 1998) find four latent factors underlying the existing symptom criteria of PTSD, rather than the three conceptual factors that appear in the diagnostic criteria (i.e., intrusion, numbing/avoidance, and hyperarousal). Most typically, in factor analytic studies, the avoidance and numbing symptoms are found to be distinct factors. Adjusting the factors so that they represent how the symptoms are found naturally seems to be an obvious course for future modifications for the DSM.

Most of the concerns expressed about these diagnostic criteria, however, are based on the fact that, although patients with PTSD meet the diagnostic criteria, they do not seem to resemble these criteria. This has led to many variations, such as complex PTSD, which focuses greatly on issues of emotional lability and instability, impaired interpersonal relations, and self-esteem. These latter symptoms can actually characterize many patients who've experienced trauma and have developed PTSD. For instance, when examined concurrently, the vast majority of people with PTSD also met diagnostic criteria for disorders of extreme stress or complex PTSD (Newman, Orsillo, Herman, Niles, & Litz, 1995). Thus, there is considerable overlap between PTSD and the constructs proposed as distinct entities.

Finally, it is valuable to understand that, in any classification scheme in science, one tries to employ the fewest number of items to discriminate one condition from the next. If we were trying to describe PTSD by the diagnostic criteria, we would most assuredly lead with anxiety and depression. Yet neither of these symptoms provides any discriminatory power to the diagnostic criteria in segregating PTSD from either mood or anxiety conditions. The symptoms of intrusion, hyperarousal, numbing, and avoidance provide the greatest levels of distinction of PTSD from similar psychological conditions.

## *The Interrelationship of Trauma and Dissociation*

Among the complex issues involved in understanding PTSD is its relationship with dissociation. Dissociative experiences overlap considerably with PTSD, leading to at least three dominant explanations for their co-occurrence. First, co-occurring PTSD and dissociation may reflect complex adaptations to trauma, particularly traumas that occur early in child development, when regulation systems are still developing (e.g., van der Kolk et al., 1996). For example, PTSD, dissociation, somatization, and affect dysregulation were highly interrelated in a sample of 395 treatment-seeking and 125 non–treatment seeking individuals exposed to trauma. Second, high (or pathological) levels of dissociation may characterize a specific subtype of PTSD (e.g., Putnam, 1997). For example, adult rape survivors who scored high on measures of dissociation 2 weeks post-rape were more likely to meet symptom criteria for PTSD *and* show suppressed autonomic physiological responses in the lab (Griffin, Resick, & Mechanic, 1997). Because PTSD is usually thought of as associated with greater physiological reactivity, the suppressed physiological finding is particularly noteworthy. Putnam, Carlson, Ross, and Anderson (1996) examined dissociative tendencies (as measured by the Dissociative Experiences Scale; DES) and PTSD among 1,566 individuals who comprised three groups: psychiatric patients, neurological patients, or typical adolescents or adults. Half of the participants diagnosed with PTSD scored in the extreme range on the DES and half in the normal range. Similarly, Briere, Scott, and Weathers (2005) reported that approximately 44% of participants diagnosed with PTSD did not have clinically elevated scores on a dissociation measure.

Third, PTSD symptoms can be conceptualized as dissociative symptoms. For example, van der Hart, Nijenhuis, and Steele (2005) propose that dissociation is not only a central feature of PTSD, but that PTSD can be reconceptualized into two categories of dissociative symptoms: positive (e.g., traumatic memories and nightmares) and negative (e.g., loss of affect, loss of memory). By this logic, high correlations between PTSD and dissociation should not be surprising, as they are part of the same underlying construct.

Still other theorists and researchers remain agnostic with regard to the reason for the relationship between concurrent PTSD and dissociation symptoms, but note the importance of dissociative responses in understanding PTSD trajectories (e.g., Halligan, Michael, Clark, & Ehlers, 2003).

## Prevalence Issues

When initially delineated in the DSM-III, PTSD was considered to be a relatively rare condition, and traumatic events were considered to be outside the range of normal human experience. In the past two decades, there has been an explosion of growth in our knowledge of exposure to traumatic events, the development of PTSD, and the conditional probability of developing PTSD if one is exposed to a specific life event. Recent epidemiological studies document high prevalence rates of exposure to traumatic events in the general population and confirm that PTSD occurs following a wide range of aversive life events. Most important, though, are the consistent findings that suggest that although exposure to potentially traumatic events is quite common, development of PTSD is relatively rare. Elucidation of the factors responsible for some people developing PTSD while others exposed to similar threatening events do not may inform our understanding of key variables in the etiology of this condition. These factors are termed risk and resilience variables.

### Post-traumatic Stress Disorder in the U.S. Population

Perhaps the most complete general U.S. population studies are those conducted by Kessler and colleagues. In the original National Comorbidity Survey (NCS; Kessler, Sonnega, Bromet, Hughes, & Nelson, 1995), a nationally representative sample of 5,877 individuals aged 15–54 years were interviewed using a structured diagnostic inventory. An overall lifetime PTSD prevalence rate of 7.8% was found, with rates for women (10.4%) more than twice that for men (5.0%). Trauma exposure estimates indicated

that about 61% of men and 51% of women were exposed to one or more traumatic events. In the National Comorbidity Survey Replication (NCS-R; Kessler et al., 2005), a nationally representative sample of 5,692 individuals were interviewed based on the Composite International Diagnostic Interview. Similar to the rates reported in the NCS, an overall lifetime PTSD prevalence rate of 6.8% was found.

Compared to the NCS and NCS-R, similar or slightly higher PTSD rates were obtained in selected, specialized samples. For example, among 21–30-year-old members of a Detroit area HMO, 39% reported experiencing a trauma and 9% met PTSD criteria (11% of women and 6% of men; Breslau, Davis, Andreski, & Peterson, 1991). Similarly, among former Miami–Dade public school students aged 18–23, 11.5% met lifetime PTSD criteria (15.5% of women and 7.5% of men; Lloyd & Turner, 2003). Further, among two American Indian tribes, lifetime PTSD rates were 14% and 16%, whereas past year rates were 5% and 6%, with higher rates consistently found among women compared to men (Beals et al., 2005).

Emphasizing the impact of sexual assault and other criminal acts, several epidemiological studies focused on documenting PTSD in women. For example, Kilpatrick, Edmunds, and Seymour (1992), in a nationally representative sample of women, learned that 13% of 4,008 participants reported a completed rape. Of those who were raped, lifetime and current PTSD rates were 32% and 12%, respectively. Importantly, Kilpatrick and his group (2008) conducted a similar survey 10 years later to learn that the prevalence of rape in the general population of women rose significantly to 18%. These rates were especially disappointing, given the implementation of policies to address date rape in the intervening decade between these two epidemiological surveys. Finally, using a national probability sample, Resnick, Kilpatrick, Dansky, Saunders, and Best (1993) estimated that 36% of women had been criminally victimized, with 14% experiencing attempted rape or molestation and 12% experiencing a completed rape. They estimated lifetime and current PTSD rates to be 12% and 5%, respectively. Among those who were exposed to criminal victimization, rates of lifetime and current PTSD were 26% and 10%.

Clearly, the prevalence of exposure to traumatic events in the United States is far more common than anticipated in 1980, when the diagnosis of PTSD was incorporated into the diagnostic nomenclature. Even more surprising are findings indicating that the rate of current PTSD in the general population

falls only behind major depression, attention-deficit hyperactivity disorder, specific phobia, and social phobia—making PTSD the fifth most common psychiatric condition in the United States (Kessler et al., 2005).

## POST-TRAUMATIC STRESS DISORDER AMONG U.S. COMBATANTS

Soldiers whom we send to fight wars and to keep peace are among those most at risk for trauma exposure and the development of PTSD. Despite the high frequency of military action and war worldwide, few countries have ever estimated the psychological toll of war. The major exception to this was the National Vietnam Veterans Readjustment Study (NVVRS; Kulka et al., 1990), which included a representative sample of 1,632 Vietnam Theater Veterans (VTVs), a matched sample of 716 Vietnam Era Veterans (VEVs), and 668 civilian comparison subjects. More than 15% of male VTVs and 9% of female VTVs met criteria for current PTSD; this survey was conducted more than 15 years after the most intense fighting in the Vietnam Theater.

In a painstaking reanalysis of the clinical data from the NVVRS, Dohrenwend et al. (2006) examined military records, newspapers, and other sources of information to confirm the reports of combat trauma among theater veterans. The purpose of the study was to reduce or eliminate recall bias of combat exposure. Using only the strictest of definitions of combat exposure (confirmed by a source other than the study participant), they found PTSD rates that were at least twice those found in the general population of American males.

Peacekeeping has its own set of stressors associated with it, including being instructed to not fire unless fired upon while instructed to guard areas that are often under tenuous control. Litz, Orsillo, Friedman, Ehlich, and Batres (1997) examined a sample of 3,461 active-duty peacekeeping military troops who served in Somalia. Shortly after their return to the United States, 8% of these soldiers reported PTSD, a rate that did not differ for men and women. Eighteen months after their return, 7% of a subsample of 1,040 veterans met criteria for delayed-onset PTSD (Gray, Bolton, & Litz, 2004).

Several studies examined the impact of service in Persian Gulf War I. For instance, Wolfe, Brown, and Kelley (1993) conducted a longitudinal study of 2,344 Gulf War I veterans and found PTSD prevalence rates of 4% for men and 9% for women. Studies using smaller convenience and reservist samples found PTSD rates in the range of 16%–19%

(Perconte, Wilson, Pontius, Dietrick, & Spiro, 1993; Sutker, Uddo, Brailey, & Allain, 1993). Among soldiers deployed during Operation Iraqi Freedom and Operation Enduring Freedom, Hoge et al. (2004) found that 6% of the Army soldiers met screening criteria for PTSD after deployment to Afghanistan, and 12% met criteria after deployment to Iraq. Among the Marine Corps soldiers deployed to Iraq, 12% met screening criteria for PTSD. More recent studies from this same group indicate that prevalence rates among returning groups are reaching 15%–20% of those deployed, with higher rates among those with multiple deployments (Bliese et al., 2008).

Given the notably high prevalence rates of PTSD among combatants, as well as findings indicating that PTSD symptoms among Vietnam veterans typically do not remit (Schnurr, Lunney, Sengupta, & Waelde, 2003), continued study of combatants is a national priority. Further substantiating the chronic course and nature of combat-related PTSD is the detailed study of the military's testing of mustard gas on soldiers during World War II. Although this testing was not commonly known until the 1990s, fully 32% of those exposed continued to exhibit full PTSD symptomatology a half century later.

After the appearance of the NVVRS in the late 1980s, there was great interest in the prevalence of PTSD among other minority groups who were involved in that war. In the Matsunaga Vietnam Veterans Project, prevalence rates of PTSD were 45% among Southwest Plains Indians, 57% for Northern Plains Indians, 38% for Native Hawaiians, and 9% among Americans of Japanese extraction; these differences appear to be largely a function of differences in war zone stress exposure (Beals et al., 2002; Friedman, Schnurr, Sengupta, Holmes, & Ashcraft, 2004). These remarkably high rates of PTSD led to multiple changes in public policy that provided additional services to many of these minority communities.

## POST-TRAUMATIC STRESS DISORDER ACROSS THE GLOBE

With increasing recognition of the health and economic costs associated with psychological morbidity across the world (Murray & Lopes, 1994), there is a growing acknowledgment of the need for regional and world estimates of psychiatric disorders, including PTSD.

Economically developed countries often observe a wide range of PTSD prevalence, perhaps owing to

differences in culture, language, experiences, and study methodology. The lowest rates of PTSD were found in Iceland among a cohort of half the birth population in the year 1931 (i.e., lifetime rate of 0.6%, with no men meeting criteria; Líndal & Stefánsson, 1993). In addition, among a representative sample of 10,641 Australian adults, past-year PTSD prevalence was estimated at 1.5%, with similar rates among women and men. Among the 57% of the sample who experienced a traumatic event, higher rates of PTSD were found among women (4%) than men (2.0%), potentially because experiencing rape or sexual molestation were the traumas most likely to result in PTSD (Creamer, Burgess, & McFarlane, 2001; Rosenman, 2002). Among Australian male Gulf War I veterans, 5% were found to have developed PTSD after the war, whereas only 1.4% of a comparison sample of veterans who did not deploy to the Gulf developed PTSD during that time (Ikin et al., 2004).

Post-traumatic stress disorder prevalence rates in less economically developed countries tend to be higher than in more developed countries. For example, among a geographically diverse sample of Mexican adults, lifetime PTSD prevalence was estimated to be 19% (Norris, Murphy, Baker, & Perilla, 2004). In addition, among adult Israeli residents, Bleich, Gelkopf, and Solomon (2003) found that 9% met criteria for current PTSD, with higher rates among women (16%) than men (2.4%). Finally, in a Palestinian sample, Punamäki, Komproe, Qouta, El-Masri, and de Jong (2005) found PTSD prevalence rates of 22% and 13% for men and women, respectively.

Substantially higher rates of PTSD are observed in those countries that are non-Western and developing. Many of these estimates were derived following periods of war and political turmoil. Examining large, fairly representative samples of men and women age 16 or older living in post-conflict, low-income countries such as Algeria, Cambodia, Ethiopia, and Gaza, de Jong et al. (2001) found high rates of PTSD in each sample (37%, 28%, 16%, and 18%, respectively). In Algeria and Cambodia, and consistent with findings in the United States, women had higher rates of PTSD than men (44% vs. 32% and 34% vs. 21%, respectively). In contrast, in Ethiopia and Gaza, women possessed similar or lower rates of PTSD compared to men (15% vs. 17% and 14% vs. 23%, respectively).

Following the bombing raids launched by the United States on Afghanistan, as well as a long history of war, conflict, and drought, Lopes Cardozo et al. (2004) studied a representative sample of disabled and nondisabled Afghan people age 15 or older. Similarly high rates of PTSD were found among the disabled and nondisabled samples (i.e., 42% and 43%, respectively). Women in both groups exhibited higher rates of PTSD than men, findings that were attributed to the widespread restrictions placed on women during the Taliban regime. Near this same time, and using a similar methodology, Scholte et al. (2004) found that 20% of persons age 15 or older in the Nangarhar province of eastern Afghanistan met criteria for PTSD, with much higher rates found among women (32%) than men (8%).

In a sample of Rwandans living in four diverse communes eight years after the 1994 genocide in that country, Pham, Weinstein, and Longman (2004) reported a 25% prevalence rate of PTSD, with higher rates again found among women than men. Interestingly, participants in this study reported particularly high rates of avoidance symptoms, an approach to anxiety management consistent with Rwandan cultural discouragement of open displays of emotion.

Norris and Slone (2007) suggest that the most significant limitations of the PTSD epidemiological literature is a lack of research in developing countries, particularly since they appear to be at elevated risk for experiencing trauma. Although international studies of trauma continue to grow, much more work is necessary. Clearly, it is unlikely that research conducted in the United States and other developed countries can be readily generalized to the developing world. Differences in experiences, cultures, resources, social structures, and coping behaviors may significantly influence the prevalence and course of PTSD among peoples.

**REFUGEES**

Fazel, Wheeler, and Danesh (2005) summarized the data across multiple studies, including a total of 5,499 adult refugees resettled in Western countries. They found substantial variability in prevalence rates (range = 3%–44%). When restricting analyses to more rigorously designed studies including at least 200 participants, the average PTSD prevalence rate was 9%.

Sack, McSharry, Clarke, and Kinney (1994) reported that 100% of 209 Cambodian adolescent refugees were exposed to atrocities such as witnessing executions and being separated from family. Kuterovac, Dyregrov, and Stuvland (1994) found similar rates among 134 youths living in Croatia.

Although long overlooked, the needs of children in war zones are now receiving considerable attention due to these ground-breaking studies of war zone exposure and its consequences.

A burgeoning literature suggests that a wide range of natural and man-made disasters can lead to the development of chronic PTSD. Green and colleagues found that 44% of survivors of the collapse of the Buffalo Creek Dam in West Virginia in the late 1970s met criteria for PTSD, and 28% of the sample still met diagnostic criteria 14 years later (Green, Lindy, Grace, & Gleser, 1990; Green, Lindy, Grace, Gleser, Leonard, et al., 1990). Similarly, McFarlane (1989) studied the effects of Australian brush fires on a sample of firefighters; PTSD prevalence rates were estimated at 32%, 27%, and 30% respectively at 4, 11, and 29 months post disaster.

Norris, Murphy, Baker, and Perilla (2004) studied the devastating 1999 floods and mudslides in Mexico. Interviewing a representative sample of 561 drawn from two affected cities, they found a combined prevalence of 24% PTSD in these two cities some 6 months following the disaster. Rates of current PTSD decreased sharply, however, as the investigators continued to monitor psychological outcomes over the next 2 years. Yet, at the 2-year mark, the prevalence of PTSD still exceeded that of the general population.

In recent years, concern regarding the psychological consequences of terrorist attacks has increased substantially. In a review of studies reporting PTSD prevalence rates following terrorist attacks, Gidron (2002) reported a mean rate of 28%. However, these studies varied greatly in subject sampling and in the timing of assessments. Following the September 11, 2001 terrorist attacks on the World Trade Center (WTC) and the Pentagon, telephone and web-based methodologies were employed to examine levels of resultant PTSD symptoms throughout the United States. Rates of PTSD generally were higher based upon regional proximity to the attacks. For example, Schlenger et al. (2002) found the prevalence of probable PTSD to be 11% in the New York City metropolitan area, but much lower in Washington D.C. (3%), other metropolitan areas (4%), and the remainder of the country (4%). In a sample of adults residing in an area of Manhattan closest to the World Trade Center, 7.5% reported symptoms consistent with a PTSD diagnosis, and 20.0% of

a subsample residing closest to the WTC reported such symptoms (Galea et al., 2002).

These are just a few of the many different types of disasters examined to date. Overall, the epidemiological literature strongly suggests that various types of disasters contribute substantially to the development of PTSD, that the prevalence is high, and that the effects for some can be long-lasting.

## Theoretical Models

A great number of PTSD models have been proposed. A few of the models that have empirical support will be described here.

### Barlow's Model of Anxiety

Keane and Barlow (2002) adapted Barlow's (2002) model of anxiety and panic to promote an understanding of the variables involved in the development of PTSD. This conceptual model suggests that both biological and psychological vulnerabilities may underlie the development of PTSD. Each of these variables may exert independent effects or may interact to increase the likelihood of exposure to a traumatic event; these factors constitute those variables responsible for the vulnerability of some to developing disorder upon trauma exposure. Extrapolating from this model, when an individual is exposed to a traumatic life event, a biological and psychological alarm occurs that leads to both conditioning of stimuli present at the time of the event and to the development of cognitions, such as anxious apprehension of a recurrence of the traumatic event. The conditioned cues and the apprehension that another event like this might occur contribute to the maintenance of symptoms (i.e., a learned alarm). These emotionally charged cues then promote the development of avoidance strategies in order to effectively minimize the experience of aversive emotional reactions. The emergence of PTSD is a function of these variables; if an individual experiences high levels of social support or he or she possesses positive coping abilities, these may influence whether PTSD develops or the severity of the PTSD when it does.

Keane and his colleagues first conceptualized PTSD using a conditioning and avoidance model of the disorder (Keane & Kaloupek, 1982; Keane, Zimering, & Caddell, 1985). Wirtz and Harrell (1987) provided some empirical support for the process of classical conditioning (i.e., learned alarms) within PTSD. They observed that victims of physical assault were less distressed 6 months after the assault if they had experienced exposure to situations or

stimuli that were part of (or resembled) the context of the original assault without experiencing another assault. Survivors who had not had the advantage of this exposure, on the other hand, maintained their distress until the 6-month measurement. This is what one would expect in classical conditioning. Other investigators have noted the importance of conditioning in the development of PTSD (Keane, Fairbank, Caddell, Zimering & Bender, 1985; Orr et al., 2000), whether the trauma is combat-related, involves a physical or sexual assault (e.g., Holmes & St. Lawrence, 1983; Kilpatrick et al., 1985; Orr, Meyerhoff, Edwards, & Pitman, 1998), or is the consequence of terrorism (Shalev et al., 2000).

In PTSD, the emotions themselves are avoided to some extent; we refer to this as a numbing of emotional responsiveness. This numbing in PTSD may very well represent avoidance of aversive emotional reactions or, in terms of Barlow's theory, avoidance of the learned emotional alarm (cf., Jones & Barlow 1991; Litz, 1992; Litz, Orsillo, Kaloupek, & Weathers, 2000). The importance of the use of the term "alarm" here is related to the distinct possibility that the event has biological and psychological concomitants. The intensity of the emotional alarm may precipitate the experience of a dissociative state, as noted earlier. It also is likely that the alarm that the individual experiences is comparable to panicking, wherein the concurrent psychological experiences may actually be, in part, dissociative in nature. Although the focus in past etiological work on this topic is on fear and the feared stimulus, future work may well focus upon a broader understanding of the psychobiological concomitants of the exposure itself. It may well be true that the alarm is more than fear and include a complex range of emotional responses.

In any case, the experience of alarm or other intense emotions in and of itself is not sufficient for the development of PTSD. Much as in other disorders, one must develop anxiety or the sense that these events, and one's own emotional reactions to them, are proceeding in an unpredictable, uncontrollable manner. When negative affect and a sense of uncontrollability occur in conjunction with one another, it increases the likelihood that anxious apprehension and rumination occurs and, thus, PTSD emerges.

As in many disorders, anxiety and related affective states can be moderated to some extent by the use of adaptive coping skills and the presence of structural and functional social support systems. In PTSD,

evidence already exists that these moderating variables play a role in determining whether the disorder develops or not. Therefore, these factors are represented explicitly in the Barlow (2002) and Keane and Barlow (2002) model of PTSD. Although it is likely that the use of adaptive coping skills and support systems mitigate many psychological disorders, the data supporting this assertion in the area of psychological trauma are especially convincing (Keane, Scott, Chavoya, Lamparski, & Fairbank 1985).

### Cognitive Model
Ehlers and Clark's (2000) cognitive model of PTSD emphasizes perceptions of threat in the onset and maintenance of PTSD symptoms. With an emphasis on appraisal processes, the authors argue that individuals suffering from persistent PTSD (relative to trauma-exposed peers without PTSD) are "unable to see the trauma as a time-limited event that does not have global negative implications for their future" (p. 320). Thus, appraisals of external and/or internal experiences lead to perceptions of ongoing threat. In turn, appraisals (e.g., "bad things always happen to me") increase avoidant behaviors, initiating a cycle in which overgeneralized fears are maintained in response to avoidance. Appraisals of post-trauma reactions can also create or maintain ongoing threat. For example, common post-trauma responses (e.g., disruptions in concentration, intrusive recollections, and irritability) may be interpreted as signs of threat to one's mental or physical well-being. Appraisals of stress responses as threatening in and of themselves can lead to efforts to suppress experiences, which paradoxically increase the feared responses. A growing number of studies document prospectively links between appraisals (e.g., negative beliefs about the self and world) and PTSD symptoms (Dunmore, Clark, & Ehlers, 2001; Ehring, Ehlers, & Glucksman, 2008). With its focus on appraisal processes, this theory lends itself nicely to cognitive interventions (Dalgleish, 2004).

In addition to appraisals, the cognitive model also highlights the role that memory problems can play in ongoing perceptions of threat (see Halligan et al., 2003). For example, trauma memories may be poorly integrated in autobiographical memory and may be less elaborate, leading to decreased associations with other thematically related material that would otherwise assist the individual with meaning-making. Problems in integration and elaboration may result in frequent triggering of intrusive memories in response to sensory (rather than thematic)

cues (Halligan et al., 2003). Further, dissociation at the time of the event may disrupt encoding of the event as it occurs. Because intrusive memories may contain sensory-specific characteristics related to how the memory was encoded (e.g., smells, body sensations), sensory cues may trigger intrusive memories. The cognitive model also suggests that stimuli from the traumatic event are closely connected to one another, as are individual responses to those stimuli. Therefore, when an individual encounters a trauma-relevant stimulus in the present, the closely connected response is also triggered. Avoidance strategies may lessen the individual's perception of threat in the short run, but block cognitive change and contribute to the maintenance of PTSD in the long run. Several empirical studies support the cognitive model's emphasis on disorganized trauma memories in PTSD. Using both cross-sectional and prospective methods, disorganized trauma memories predicted concurrent and prospective PTSD symptoms in adult assault survivors, even after controlling for event severity (Halligan et al., 2003). Further, encoding that focuses on sensory and perceptual dimensions of events with relatively less elaboration and meaning-making has been associated with PTSD symptom development among motor vehicle accident survivors (Murray, Ehlers, & Mayou, 2002).

### Dual Representation Theory of Post-traumatic Stress Disorder

The dual representation theory (DRT) of PTSD (e.g., Brewin, 2001, 2003; Brewin, Dalgleish, & Joseph, 1996) has important implications for understanding the nature of PTSD experiences, particularly the oscillation between seemingly inaccessible trauma-related information and all-too-accessible intrusive memories. Implying the existence of multiple memory systems (Brewin, 2001), the DRT proposes that trauma-related memories for emotionally arousing events are stored in at least two representational formats: as verbally accessible and situationally accessible memories (VAMs and SAMs). Verbally accessible memories comprise trauma narratives that the individual can consciously bring into awareness and about which the person can make statements (generally referred to as declarative memory). Because information stored in VAMs is integrated with other autobiographical information, VAMs can interact with other information about the self. Importantly, VAMs can be updated and recognized as existing at a particular point in time relative to the past, present, and future.

Situationally accessible memories are not verbally accessible (i.e., nondeclarative). Therefore, SAMs are unavailable for the sort of integration and meaning-making characteristic of representations in VAMS. Situationally accessible memories are theorized to include lower-level perceptual information about the trauma scene and/or about somatic experiences during the trauma. These lower-level perceptual memories do not get updated based on other information in autobiographical memory, time, or context (e.g., relative to the past, present, and future), making them essentially time-locked. Exposure, therefore, to traumatic reminders in the form of sights, sounds, and smells makes it difficult for the individual to control SAMs. When SAMs are activated, the accompanying emotions are likely to be those experienced at the time of the event.

From a DRT perspective, the intrusive memories that are characteristic of PTSD are represented in SAMs, disconnected from other aspects of autobiographical memory and verbal expression. Brewin et al. (1996) suggest that premature inhibition of processing trauma memories may result in impaired memory for the trauma or trauma-related material. Thus, the dual representation view of PTSD provides an important framework for understanding inconsistencies in memory (too much and too little access) that can otherwise appear inconsistent within a single individual. For example, when trauma representations are activated in SAM, the memory will be sensory in nature, disintegrated from higher-level representations, and relatively fixed in time. Further, the unprocessed emotions from the original traumatic event will be activated. A series of creative laboratory studies provide empirical support for the DRT model (e.g., Holmes, Brewin, & Hennessey, 2004).

In his 2001 review, Brewin places the DRT in the context of the neuroscience of memory, fear, and PTSD, particularly in relation to the hippocampus and amygdala, key elements in the limbic system. Brewin argues that flashbacks in the immediate aftermath of trauma exposure provide opportunities to transfer perceptual information from the SAM system to the VAM system. For example, if the individual focuses on perceptual details in flashbacks while the trauma-related representations are active in working memory, information can be recoded into VAMs, mediated by the hippocampus. As this information is recoded, contextual and temporal information can be integrated with support from the hippocampus. As the perceptual information is recoded to provide temporal information indicating that the danger is in the past (assuming the present

is safe), the hippocampus and prefrontal cortex can inhibit amygdala activity, thus stopping the fear response. As these representations are repeatedly activated in the hippocampus, information can be consolidated in the cortex, which is otherwise slow to update and integrate radically new information (such as what a trauma represents). Failure to create VAMs renders sensory and perceptual information isolated in the SAM system. Because representations in the SAM system are prone to activation following trauma cues, activation of the amygdala and fear response would be expected to continue. Further, the slow-changing, higher-level cortical systems cannot integrate the SAM-mediated information, leading to a lack of inhibition from the cortical structures to the amygdala. This model fits nicely with recent hippocampal findings (see the section "Abnormalities in Brain Structure and Function").

To the extent that working memory is implicated in the transfer of information from the SAM to VAM system (Brewin, 2001), deficits in executive function may place individuals at risk for PTSD. Consistent with this view is a growing body of work documenting disruptions in executive function among trauma-exposed adults (El-Hage, Gaillard, Isingrini, & Belzung, 2006; Navalta, Polcari, Webster, Boghossian, & Teicher, 2006; Stein, Kennedy, & Twamley, 2002), including those who report PTSD (e.g., Foa, Feske, Murdock, & Kozak, 1991; Kremen et al., 2007; McKenna & Sharma, 1995; Parslow & Jorm, 2007; Uddo, Vasterling, Brailey, & Sutker, 1993) and dissociative (e.g., DePrince & Freyd, 1999; Simeon et al., 2006) symptoms. Working memory deficits have also been documented among children in relation to violence exposure (DePrince, Weinzierl, & Combs, in press), PTSD diagnosis (Beers & De Bellis, 2002), and dissociative symptoms (Cromer, Stevens, DePrince, & Pears, 2006). Brewin's model provides a framework for how such deficits in executive function might affect consolidation and integration of trauma memories, and in turn, the development and maintenance of PTSD.

### The Schematic, Propositional, Analogue, and Associative Representational Systems Model

Like the DRT model, the Schematic, Propositional, Analogue, and Associative Representational Systems (SPAARS) model of PTSD is a multirepresentational model (Dalgleish, 2004). The SPAARS framework points to two critical characteristics of events that lead to PTSD. These events are: (1) significantly inconsistent or discrepant with existing schema of the self and world; and (2) likely to evoke intense emotion, particularly fear, either automatically or via appraisal processes (Dalgleish & Power, 2004). Because events are discrepant with existing schemas (or beliefs, representations) of the self and world, the representation of the trauma remains active in an effort to integrate this information via assimilation and accommodation into preexisting schemas; reexperiencing symptoms result from ongoing activation of the trauma representations. In turn, people attempt to avoid trauma-related cues and representations to mitigate the reexperiencing symptoms and related distress. As this process unfolds, the representation continues to elicit trauma-related emotions that lead to the hyperarousal symptom of PTSD. Further, the SPAARS model specifies different levels (propositional, analogical, and schematic) at which representations can be encoded. Associative representations then link information across these levels. Repeated analysis of the incompatibility of these lower-level representation levels with higher-level schemas likely contributes to the maintenance of an ongoing sense of threat.

### Betrayal Trauma Theory

While the Cognitive, DRT, and SPAARS models emphasize fear and threat, betrayal trauma theory (BTT) highlights the importance of social relationships in understanding post-traumatic outcomes (Freyd, 1994, 1996, 2001; Freyd, DePrince, & Gleaves, 2007). The theory was initially developed as a framework for understanding *why* victims of abuse would report disruptions in memory for the event, particularly memory impairment. As noted by Freyd et al. (2007), "the phrase *betrayal trauma* refers to a social dimension of trauma, independent of the individual's reaction to the trauma" (p. 297). Betrayal Trauma Theory proposes that the way in which events are processed and remembered will be related to the degree to which a negative event represents a betrayal by a trusted, needed other (Sivers, Schooler, Freyd, 2002). In recent years, the theory has been extended and developed, and other responses such as alexithymia, depression, and anxiety have been considered (e.g., Goldsmith & Freyd, 2005).

Betrayal Trauma Theory (Freyd, 1996) offers an important framework to help us understand key PTSD findings. For example, women, relative to men are more likely to report interpersonal traumas perpetrated by close others (Goldberg & Freyd, 2006), and to meet criteria for PTSD (Norris, Foster, & Weisshaar, 2002). Betrayal Trauma Theory

predicts that higher levels of dissociation should be associated with interpersonal traumas perpetrated by close others relative to other types of events (see Freyd et al., 2007). In turn, the Ehlers and Clark cognitive model links dissociation to disorganized memories involved in the onset of PTSD (Halligan et al., 2003). Thus, to the extent that closeness to the perpetrator is linked to dissociative responses (e.g., Chu & Dill, 1990; DePrince, 2005; Plattner et al., 2003), the cognitive model can help explain how that dissociative response relates to disorganized memories and PTSD.

Betrayal Trauma Theory also implicates shareability theory (see Freyd, 1996), which is relevant to the DRT model. The DRT model highlights the importance of recoding and integration of SAM-mediated information into the VAM system (Brewin, 2001). Such recoding requires activating the trauma representations in working memory and sustained attention to the content (Brewin, 2001). By extension, avoidance processes would inhibit or preclude such recoding. Complementing this view, shareability theory (see Freyd, 1996) points to the importance of sharing information for the structure of mental representations. In order to share information, Freyd argued that we recode fine-grained perceptual information about events to more discrete and abstract forms. Shareability theory, then, predicts that memory for events that have never been discussed will be qualitatively different from those that have been shared with others. According to BTT, traumas high in betrayal are less likely to be shared (see Foynes, Freyd, & DePrince, 2009). In the absence of sharing, the original perceptual information is likely to remain intact without the recoding that occurs when memories are shared. Consistent with a DRT perspective, perceptual information may remain as a SAM, where it is easily activated by trauma-related perceptual cues.

Thus, multiple theories are proposed to understand the development and maintenance of PTSD. Each theory provides a unique perspective, one that emphasizes aspects of the condition. Each theory also points to directions for intervening to promote recovery and lasting change.

## Psychopathology
### *Cognitive Science*
#### ATTENTION AND POST-TRAUMATIC STRESS DISORDER
The modulation of attention to emotional (particularly threat-related) stimuli has garnered a great deal of interest in the PTSD literature. In several studies,

adults diagnosed with PTSD show difficulty controlling interference from trauma-related stimuli in the emotional Stroop task, relative to control groups (McKenna & Sharma, 1995, Foa et al., 1991; Williams, Watts, MacLeod, & Mathews, 1997). In this task, participants are asked to name the colors in which words are printed while ignoring the words themselves. A positive emotional Stroop effect happens when participants are slower to name the color of trauma-relevant words relative to a baseline condition, compared to their peers. Recently, Kimble et al. (2009) argued that the robustness of the Stroop effect may be overstated because of failure to publish null findings. Using dissertation abstracts to address the "file drawer" problem in meta-analysis, Kimble demonstrated that the rates of positive findings that make their way into the literature are significantly higher than in well-implemented, but unpublished, dissertations.

Regardless of the size of the Stroop effect, attentional biases among adults diagnosed with PTSD are generally assumed to maintain a sense of ongoing threat (see Ehlers and Clark, 2000 for a discussion of the consequences of ongoing threat). This premise is supported by the observation that trauma exposure in the absence of symptoms does not appear to be associated with attentional biases in adults. For example, Elsesser, Sartory, and Tackenberg (2005) found no evidence that the trauma-exposed adults show biases toward threat images relative to non–trauma exposed controls. Children diagnosed with PTSD or high levels of dissociative symptoms also appear to process threat-related information differently than do comparison groups (e.g., Becker-Blease, Freyd, & Pears, 2004; Dalgleish, Moradi, Taghavi, Neshat-Doost, & Yule, 2001; Moradi, Taghavi, Neshat-Doost, Yule, & Dalgleish, 1999). For example, Dalgleish and colleagues (2001) have documented Stroop interference caused by trauma-related information among children with PTSD.

#### EXPLICIT MEMORY AND POST-TRAUMATIC STRESS DISORDER
Cognitive scientists have also examined memory performance in the laboratory, documenting explicit memory deficits for neutral information in relation to PTSD. For example, individuals diagnosed with PTSD related to a range of trauma types (e.g., combat, abuse) perform worse on measures of explicit memory performance on standardized neuropsychological tests relative to no-PTSD and non–trauma exposed peers (e.g., Bremner, Randall, Scott, Capelli, et al., 1995; Bremner et al., 2003a; Sutker, Winstead,

Galina, & Allain, 1991; Yehuda, Keefe, Harvey, & Levengood, 1995). However, we do not know whether explicit memory impairments in adults are a consequence of *or* a risk factor for PTSD. Although relatively little work has examined basic memory functioning in children, at least one study demonstrates that children diagnosed with PTSD show deficits in memory relative to a no-trauma comparison group (Beers & De Bellis, 2002). This study suggests that PTSD-related explicit memory deficits may occur fairly early in development.

Explicit memory for trauma-relevant information appears to be heightened among adults diagnosed with PTSD in laboratory tasks (e.g., Litz et al., 1996; Paunovic, Lundh, & Öst, 2002; Vrana, Roodman, & Beckham, 1995). For example, Holocaust survivors diagnosed with PTSD recalled fewer paired-associates overall (consistent with the literature on poor explicit memory reviewed earlier), but more Holocaust-related word pairs than neutral word pairs, relative to Holocaust-exposed control participants without PTSD whose recall was unaffected by word type (Golier, Yehuda, Lupien, & Harvey, 2003). Thus, PTSD is associated with both general deficits in explicit memory performance and heightened memory for trauma-related stimuli in laboratory tasks. How laboratory tasks correspond to autobiographical memory in PTSD remains unclear. In a related review, Brewin (2007) noted the importance of distinguishing between voluntary (intentional, conscious recollection) and involuntary (memory intrusions and flashbacks) autobiographical memory for trauma in clinical and nonclinical populations. This distinction is likely important in interpreting heightened voluntary memory in lab tasks relative to voluntary and involuntary autobiographical memories in daily life.

### PHYSIOLOGICAL REACTIVITY

Psychophysiological symptoms are a prominent feature of PTSD. According to criteria outlined in the DSM-IV (APA, 1994), there are several ways in which heightened psychophysiological activity would be expected in PTSD. First, an exaggerated startle response to startling sounds would be predicted. Second, a heightened psychophysiological activity during resting periods would be expected, which would be consistent with the hyperarousal symptom cluster of the disorder. Third, elevated psychophysiological reactivity would be expected during exposure to cues (either internal or external) that symbolize or resemble an aspect of the traumatic event, consistent with the reexperiencing symptom cluster of PTSD and specifically relevant to the DSM-IV (APA, 1994) PTSD symptom of physiological reactivity on exposure to trauma cues.

A wealth of literature investigates whether elevations in psychophysiological activity and reactivity is associated with PTSD. Indeed, there have been consistent findings demonstrating that individuals with PTSD show elevated psychophysiological activity (e.g., heart rate, skin conductance, facial electromyography) during resting periods, heightened psychophysiological reactivity (e.g., eye blink startle reflex, heart rate, skin conductance, and slower skin conductance habituation) to startling sounds, and heightened psychophysiological responding (e.g., heart rate, skin conductance, systolic blood pressure, facial electromyography) to trauma cues relative to individuals without PTSD, including individuals who have had similar trauma exposure but have not developed PTSD (Keane et al., 1998; Malloy, Fairbank, & Keane, 1983).

An excellent quantitative review of this literature was recently conducted by Pole (2007). Pole's meta-analysis included 58 resting baseline studies, 25 standardized cue studies, and 22 idiographic trauma cue studies that compared adults with and without PTSD on a variety of psychophysiological measures. Findings indicated reliable associations between PTSD and laboratory measures of psychophysiological activity and reactivity. Specifically, PTSD was associated with aggregate indices of higher resting arousal (unweighted mean effect size $r = .16$). Post-traumatic stress disorder was also associated with aggregate indices of larger responses to startling sounds (unweighted mean effect size $r = .24$). As expected, PTSD was associated with aggregate indices of larger responses to standardized trauma cues and larger responses to idiographic trauma cues (unweighted mean effect size $r = .37$ for both standardized and ideographic trauma cues). It should be noted that large effect sizes were observed for psychophysiological responding to trauma cues, whereas effect sizes were small for resting psychophysiological activity and startle responding.

There is some evidence that psychophysiological symptoms in PTSD may be affected by several factors, including PTSD symptom severity (Orr & Roth, 2000). In his meta-analysis, Pole examined moderators that might affect psychophysiological responding in PTSD. Findings indicated that greater PTSD symptom severity was associated with larger effect sizes and greater diagnostic sensitivity of diagnostic prediction. This finding likely reflects the fact that there is considerable heterogeneity among PTSD samples.

Psychophysiological symptoms do not need to be endorsed in order to meet diagnostic criteria for PTSD. However, the more symptoms endorsed, the great the likelihood that psychophysiological symptoms will be endorsed.

Another factor that has been speculated to influence psychophysiological responding is the manner in which PTSD is diagnosed. Pole observed that larger effect sizes and greater diagnostic specificity were obtained when earlier versions of the DSM were applied. The critical change in PTSD criteria from the DSM-III to the DSM-IV is how a traumatic event is defined. In DSM-III, a traumatic event would involve direct threat to oneself. In contrast, the definition of a traumatic event in DSM-IV has been expanded to include threats to physical integrity of the self and witnessing serious injury or harm to others (APA, 1994). Given that psychophysiological abnormalities that are observed in PTSD are thought to reflect psychophysiological responses that occurred at the time of the trauma, it is reasonable to assume that learning about an injury of another person would produce less psychophysiological responding than a direct life threat. On the other hand, technical advances in psychophysiological assessment may account for the differences in effect sizes between earlier and later studies.

Contrary to prior speculation, Pole found that anticipatory anxiety does not account for the elevated resting psychophysiological activity observed in PTSD individuals. Specifically, Pole reported that effect sizes were larger when baseline was followed by no challenge than when it was followed by personal trauma reminders. Another noteworthy finding from this review is that psychoactive medication did not influence the aggregate psychophysiological effects. Pole was unable to examine the effect of dissociation on psychophysiological symptoms, as studies did not typically include characterization of their sample in terms of dissociation. This is unfortunate because there is some evidence that high levels of dissociation are related to reduced psychophysiological responding (e.g., Griffin et al., 1997; Pole, 2007). Another potential moderating factor that Pole did not examine is comorbid depression. There is some evidence that the presence of comorbid depression produces attenuated psychophysiological reactivity in individuals with PTSD (Cuthbert et al., 2003), which is important given the high rate of comorbid depression among PTSD samples (Keane & Wolfe, 1990; Kulka et al., 1990).

Importantly, individuals with anxiety disorders other than PTSD do not show heightened psychophysiological reactivity to trauma cues, including cues to traumas they have experienced, such as combat (e.g., Pitman et al., 1990). Moreover, relative to individuals without PTSD, individuals with PTSD do not show heightened psychophysiological reactivity to nontrauma stressful or fear-evoking stimuli (Cuthbert et al., 2003; Orr, Meyerhoff, Edwards & Pitman, 1998; Shalev, Orr, & Pitman, 1993). Thus, the heightened psychophysiological response pattern to trauma cues for PTSD individuals does not appear to be attributable to a nonspecific sensitivity to stress and/or fear cues.

Heightened psychophysiological responding also appears to be useful in predicting the development and persistence of PTSD. For example, Shalev and colleagues (1998) found that elevated heart rate in the emergency room immediately following trauma exposure was predictive of the development of PTSD. Blanchard et al. (1996) found that individuals with PTSD that did not remit within 1 year of a motor vehicle accident (MVA) had elevated heart rate during a trauma recall task that took place within the first 4 months following the MVA, compared to individuals who remitted within the first year following the MVA.

Taken together, psychophysiological symptoms (particularly heightened reactivity) are prominent features of PTSD and represent several diagnostic criteria of the disorder. Moreover, the empirical literature supports the existence of these psychophysiological symptoms in PTSD, and there is some evidence that heightened psychophysiological responding to trauma cues is predictive of the development and persistence of the disorder. Yet, within clinical practice and research there is little to no actual use of psychophysiological measurement.

## Psychobiology of Post-traumatic Stress Disorder
### Psychobiological Abnormalities

Key psychobiological mechanisms that are impaired in PTSD include sympathetic nervous system (SNS) activation, hypothalamic-pituitary-adrenocortical (HPA) mobilization, acoustic startle response, and fear conditioning. Sympathetic nervous system activation has been referred to as the "fight-or-flight response" and is a reaction in which muscular systems are mobilized to react to a significant threat. Individuals with PTSD exhibit abnormal increases in SNS reactivity, as well as in adrenergic dysregulation. Specifically, they exhibit autonomic hyper-responsiveness to both neutral and trauma-related stimuli, they show elevated urinary catecholamine levels, a downregulation of $\beta$- and $\alpha_2$-adrenergic

receptors, and they display increased reactivity to an $\alpha_2$-antagonist, yohimbine, which can provoke panic attacks and flashbacks in individuals with PTSD, but not in non-PTSD individuals (Shiromani, Keane, & LeDoux, 2009).

The HPA mobilization response is another fundamental response that promotes successful coping with stressful events and is dysregulated in PTSD (Yehuda, 2001). Specific abnormalities in individuals with PTSD include lower urinary cortisol levels, elevated lymphocyte glucocorticoid receptor levels, and dexamethasone supersuppression.

The acoustic startle response is a sequence of muscular and autonomic responses that alert an organism of impending threat and, thus, promotes survival. As noted previously, an exaggerated startle response is one of the diagnostic symptoms of PTSD, and individuals with PTSD display shorter latency and increased amplitude of the acoustic startle response, significant loss of the normal inhibitory modulation of the startle response, and resistance to habituation of the startle response (Orr & Roth, 2000).

Abnormalities in fear conditioning are also found commonly in individuals with PTSD. Fear conditioning is an adaptive mechanism whereby organisms learn to preserve information about previous threats in order to promote future survival. Several brain structures and functions have been shown to play a critical role in normal fear conditioning, and evidence indicates abnormalities in these structures and functions in PTSD. These abnormalities are described here.

## ABNORMALITIES IN BRAIN STRUCTURE AND FUNCTION

Over the past decade, neuroimaging studies have substantially advanced our understanding of the key brain systems in the pathophysiology of PTSD. As noted previously, the three brain regions that have emerged as critical in PTSD include the amygdala, medial prefrontal cortex, and the hippocampus. The amygdala is involved in the assessment of threat-related stimuli and/or biologically relevant ambiguity, and is necessary for the process of fear conditioning (Fendt & Fanselow, 1999; LeDoux, 2000). Individuals with PTSD are hypervigilant to potential threats in their environment, and they display relatively heightened acquisition of conditioned fear. Consequently, there has been speculation that the amygdala is hyper-responsive in PTSD, and functional neuroimaging studies support this speculation (e.g., Bryant et al., 2005; Driessen et al., 2004; Hendler et al., 2003; Shin et al., 2004).

The medial prefrontal cortex includes the anterior cingulated cortex, subcallosal cortex, and medial frontal gyrus. The medial frontal cortex is well connected to the amygdala in primates (e.g., Chiba, Kayahara, & Nakano, 2001; Ghashghaei & Barbas, 2002) and is involved in the process of extinction of fear conditioning and the retention of extinction (Morgan, Romanski, & LeDoux, 1993; Quirk, Russo, Barron, & Lebron, 2000). However, extinction does not occur normally when the medial frontal cortex is damaged. Given that individuals with PTSD display persistently inappropriate fear responses and diminished extinction of conditioned fear responding in the laboratory (e.g., Orr et al., 2000; Rothbaum, Kozak, Foa, & Whitaker, 2001), some have proposed that the medial prefrontal cortex is impaired in PTSD. Neuroimaging studies have found reduced cortical volumes and neuronal integrity (e.g., Rauch et al., 2003; Woodward et al., 2006; Yamasue et al., 2003), and decreased function in medial prefrontal structures among individuals with PTSD. It is notable that individuals with PTSD who dissociated during traumatic narratives show greater activation of medial prefrontal cortex relative to non-PTSD control participants. In contrast, PTSD participants who did not dissociate during a trauma narrative display relatively less activation of prefrontal medial cortex relative to the control participants (Lanius et al., 2002; Lanius et al., 2001). These findings underscore the importance of examining how brain abnormalities might be different for PTSD individuals with and without dissociative symptoms.

The third brain region of interest in PTSD is the hippocampus. The hippocampus is involved in explicit memory processes and the encoding of context during fear conditioning (Corcoran & Maren, 2001; Eichenbaum, 2000). There is also evidence that the hippocampus interacts with the amygdala during the encoding of emotional memories (e.g., Dolcos, LaBar, & Cabeza, 2004). Animal research suggests that hippocampal damage and memory impairment can result from extreme stress and high levels of stress-related hormones, such as cortisol (e.g., Sapolsky, Uno, Rebert, & Finch, 1990; Watanabe, Gould, & McEwen, 1992). Neuroimaging studies demonstrate that PTSD is associated with memory impairment, reduced hippocampal volumes, and abnormal hippocampal function (e.g., Bremner, Randall, Scott, & Bronen, 1995; Bremner et al., 2003a; Gurvits et al., 1996; Villarreal et al., 2002; Winter & Irle, 2004). Recent hippocampal studies using twin methods indicate that hippocampal

irregularities may act as risk factors for (rather than consequences of) trauma exposure (Pitman et al., 2006). Although specific hippocampal volume reductions have not replicated consistently in children, maltreated children (particularly those diagnosed with PTSD) appear to have smaller total brain and/or cerebral volumes than their peers (Watts-English, Fortson, Gibler, Hooper, & De Bellis, 2006). See Watts-English and colleagues (2006) for a review of developmental issues in brain maturation and trauma.

Based on the available evidence, the neurocircuitry model of PTSD posits that the amygdala is hyper-responsive, the medial prefrontal cortex is hyporesponsive, and the medial prefrontal cortex and the hippocampus fail to inhibit the amygdala. Although substantial advances have been made in our understanding of the neurocircuitry of PTSD, many issues need to be addressed. For instance, neuroimaging studies have typically compared individuals with PTSD to individuals without PTSD. As a result, we know very little about the specificity of brain abnormalities to PTSD versus comorbid psychiatric disorders or other anxiety disorders. There is some evidence that PTSD individuals with dissociative symptoms may display different brain abnormalities compared to those without dissociative symptoms (e.g., Lanius et al., 2002). However, only a handful of studies have investigated how dissociation might influence brain abnormalities in PTSD. It would also be useful to examine whether brain abnormalities observed in PTSD resolve with effective treatment. The functional relationship between brain structures in PTSD also needs additional investigation. Another area needing further investigation is whether the brain structure, chemistry, and function vary during the course of the disorder. Moreover, it remains uncertain whether the brain abnormalities observed in PTSD represent a preexisting risk factor for the development of PTSD, or whether these brain abnormalities represent markers for the disorder. Longitudinal and twin studies will be critical in providing information in these areas.

## Risk and Resiliency Trajectories

A major challenge for the trauma field has been to identify the individual, social, and cultural factors that increase risk for chronic PTSD and related impairment in functioning. Previous studies (Brewin et al., 2000; Ehring et al., 2006; King, King, Foy, Keane, & Fairbank, 1999; Nemeroff et al., 2006; Ozer et al., 2003; Sharkansky et al., 2000; Wolfe, Erickson, Sharkansky, King, & King 1999; Vogt &

Tanner, 2007) highlight the complexity of predicting who will and will not develop long-term PTSD.

Risk and resilience factors include, but are not limited to, the quality of the victim's early family environment, age at trauma exposure, history of prior adversity, severity of trauma exposure, breadth and strength of the social support network, exposure to additional life stressors, and individual difference characteristics such as coping repertoires, hardiness, and neurobiology. Studies also convincingly demonstrate that preexisting psychopathology may increase the risk for PTSD following exposure to a traumatic event (Bowman, 1997; Kessler et al., 1995; Kessler et al., 1999; Schlenger et al., 1992).

Two meta-analyses of the predictors of PTSD have been published (Brewin, Andrews, & Valentine, 2000; Ozer et al., 2003). With respect to historical or static predictors, both Brewin et al. (2000) and Ozer et al. (2003) found that family history of psychopathology, gender, age, race, and prior trauma exposure generally predicted a small but significant amount of variance of PTSD (average weighted effect sizes ranging from $r = .05$ to .19). With respect to trauma severity and psychological processes occurring during or immediately after the trauma, Brewin et al. (2000) found a small to medium weighted effect size of $r = .23$ for the association between trauma severity and PTSD severity, and Ozer et al. (2003) found a small to medium average weighted effect size of $r = .26$ for the strength of the relationship between perceived life threat and PTSD. Ozer et al. (2003) separately examined the relation between peritraumatic emotional response (e.g., fear, helplessness, horror, guilt, shame) and PTSD and found a similar effect size ($r = .26$). Ozer et al. (2003) also found a medium average weighted effect size ($r = .35$) for the strength of the relation between peritraumatic dissociation and PTSD. Regarding the contribution of post-trauma factors to the development and maintenance of PTSD, Ozer et al. (2003) learned that perceived social support following the traumatic event was associated with PTSD symptoms, with an average effect size falling in the small to medium range ($r = -.28$). Similarly, Brewin et al. (2000) found an average weighted medium effect size ($r = -.40$) for the relations between social support and PTSD symptoms.

Although we have learned a great deal about predictors of PTSD from the studies on which these meta-analyses are based, a serious limitation of the existing research is that most of these studies employed a cross-sectional methodology. As such,

results of these studies are not able to provide definitive information regarding whether the aforementioned variables are actually causal risk factors and the true extent to which these variables confer risk for PTSD. Prospective methodologies allow for stronger causal inferences to be made regarding the role of various risk and resilience variables in the etiology of PTSD. Recently, numerous investigators employed prospective methods to further examine the role of a few mechanisms thought to be particularly important to the development and maintenance of PTSD in the wake of trauma. More specifically, these investigations focused upon the importance of the emergence of ASD following trauma, peritraumatic dissociation, physiological reactivity immediately following trauma, neuropsychological functioning, and cognitive style.

With respect to the predictive importance of ASD, although initial findings from prospective studies supported the contention that an ASD diagnosis may confer risk for subsequent PTSD, a recent multisite prospective investigation showed that the majority of those who were admitted to hospital trauma centers and go on to develop PTSD do not initially meet criteria for ASD (Bryant, Creamer, O'Donnell, Silove, & McFarlane, 2008). This finding suggests that the ASD diagnosis may have limited utility in predicting subsequent PTSD.

Regarding the role of peritraumatic dissociation, Shalev, Peri, Canetti, and Schreiber (1996) found that degree of peritraumatic dissociation predicted a diagnosis of PTSD 6 months after the trauma, over and above all other predictors. More recently, though, Hagenaars, van Minnen, and Hoogduin (2007) demonstrated that the influence of peritraumatic dissociation disappeared after controlling for initial PTSD symptoms. These results are consistent with other research showing that the predictive power of peritraumatic dissociation is significantly reduced once initial PTSD symptoms are accounted for (Marshall & Schell, 2002; Marx & Sloan, 2005). It may not be the dissociative aspects of the experience at all, but rather the terrifying elements of the alarm associated with panic.

With respect to the prospective role of psychophysiological reactivity in the development of PTSD, Shalev et al. (1998) examined the heart rate and blood pressure of civilian trauma survivors upon admission to a hospital emergency room. Results showed that elevated heart rate upon admission as well as 1 week later significantly predicted later PTSD status. These results are consistent with other research with adult trauma survivors (e.g., Bryant, Harvey,

Guthrie, & Moulds, 2000, 2003; Kuhn, Blanchard, Fuse, Hickling, & Broderick, 2006), as well as more recent research showing that elevated heart rate at emergency room admission among children predicted PTSD symptoms 6 months later (De Young, Kenardy, & Spence, 2007). Guthrie and Bryant (2005) examined the extent to which pretrauma startle response prospectively predicted post-trauma PTSD symptomatology among firefighters. Findings showed that pretrauma startle response predicted both post-trauma startle responding and that pretrauma skin conductance response to startle predicted post-trauma PTSD symptom severity.

In the first prospective investigation of the relationship between pre-trauma neuropsychological functioning and PTSD symptoms, Parslow and Jorm (2007) indicated that greater pre-trauma verbal working memory was associated with lower post-trauma PTSD symptoms among a civilian sample of natural disaster survivors. However, pre-trauma PTSD symptom levels were not assessed in this study, and the measure that was used to assess PTSD symptomatology did not assess PTSD avoidance or emotional numbing symptoms. Further, Parslow and Jorm did not assess visual memory performance. More recently, Marx, Doron-LaMarca, Proctor, and Vasterling (2009) examined the influence of predeployment memory performance on postdeployment PTSD symptom outcomes in a sample of deployed active-duty Army soldiers. As part of a larger longitudinal study, each participant completed baseline measures of visual and verbal memory and baseline and postdeployment self-report measures of PTSD symptom severity. Results revealed that pre-trauma immediate recall of visual information was associated with postdeployment PTSD symptom severity, even after controlling for predeployment PTSD symptom levels, combat intensity, age, gender, and test–retest interval. Marx et al. also reported an interaction between predeployment PTSD symptom severity and predeployment immediate visual recall and verbal learning, indicating that neurocognitive performances were more strongly (and negatively) associated with residualized postdeployment PTSD symptoms at higher levels of predeployment PTSD symptoms. These findings highlight the potential role of pre-trauma neurocognitive functioning in moderating the effects of trauma exposure on PTSD symptoms.

Other prospective studies also support the notion that cognitive style factors may be crucial to the onset and maintenance of PTSD following trauma exposure in both children and adults (e.g., Bryant,

Salmon, Sinclair, & Davidson, 2007; Kleim, Ehlers, & Glucksman, 2007; O'Donnell, Elliott, Wolfgang, & Creamer, 2007). Specifically, research demonstrates that data-driven processing during the trauma, negative interpretations of intrusive memories, rumination, and thought suppression are all important predictors of post-trauma psychopathology (Ehlers, Mayou, & Bryant, 2003; Mayou, Ehlers, & Bryant, 2002). Another recent study by Ehring, Ehlers, and Glucksman (2008) even showed that various cognitive variables predicted PTSD and depression in disorder-specific ways.

## Assessment Methods and Prediction of Post-traumatic Stress Disorder

With elevated prevalence rates and the debilitating nature of PTSD, mental health professionals have directed efforts to the development of measures to evaluate the presence and severity of PTSD. As a result of these efforts, we now have numerous psychometrically sound self-report scales (e.g., Posttraumatic Stress Diagnostic Scale; Foa, Cashman, Jaycox, & Perry, 1997, and the PTSD Checklist; Weathers, Litz, Herman, Huska, & Keane, 1993) and interview-based instruments (e.g., Clinician-Administered PTSD Scale; Blake et al., 1995; Weathers, Keane, & Davidson, 2001, and the PTSD Symptom Scale-Interview; Foa, Riggs, Dancu, & Rothbaum, 1993) for assessing PTSD with excellent sensitivity and specificity. These measures generally produce diagnostic utility rates of around .90.

Many of these self-report instruments are helpful in screening for the possible presence of PTSD in primary care and other nonspecialty health-care settings. Such instruments are useful in the context of mass trauma, and have important implications for providing services that may ultimately prevent the development of PTSD following trauma exposure. In his excellent review of PTSD screening measures, Brewin (2005) noted that screening with a few items referring to core PTSD symptoms may be effective in screening for PTSD, and that measures with fewer items, simpler response scales, and simpler methods of scoring do as well as or better than other measures in screening for PTSD. Since Brewin's review, additional research has explored the extent to which successful screening for PTSD can occur using even shorter screening instruments (Kimerling et al., 2006; Lang & Stein, 2005). For example, Bliese et al. (2008) assessed the diagnostic efficiency of the four-item Primary Care Posttraumatic Stress Disorder Screen (PC-PTSD) as a screening tool for deployed active-duty soldiers. Results showed that both the PC-PTSD and PTSD Checklist had sound diagnostic efficiency rates.

Importantly, symptom-based screening measures are inherently limited in their ability to promote the prevention of PTSD due to their reliance on the presence or absence of current symptoms. Measures that quantify information about risk and resilience factors that influence long-term adjustment to trauma exposure may be employed to actually identify those who may be prone to develop PTSD following trauma before symptoms actually manifest. Such a tool would be useful from a true primary prevention perspective and would reduce overall health-care utilization by PTSD patients. In a recent example of such an approach, O'Donnell and colleagues (2008) developed and validated a screening instrument that identifies, during hospitalization, adults at high risk for developing PTSD and/or major depression. Participants completed a pool of questions representing 13 constructs of vulnerability during hospitalization and were then reassessed for PTSD and major depression 12 months later. The data were then split into two subsamples, with data from the first subsample used in factor analyses to derive the test items. These test items were then cross-validated on the second subsample. Receiver–operating characteristic curves showed that the resulting Posttraumatic Adjustment Scale had a sensitivity of .82 and a specificity of .84 when predicting PTSD, and a sensitivity of .72 and a specificity of .75 in predicting posttraumatic major depression.

In another recent effort, Marx et al. (2008) developed and tested a similar screening instrument for combat-related PTSD. Data were taken from the responses of 1,081 Vietnam era veterans who participated in VA Cooperative Study (see Keane et al., 1998). Participants were administered a comprehensive assessment battery, including structured interviews and self-report measures. They supplied information on a broad array of topics related to prewar background and functioning, military and war zone experiences, and postwar circumstances, life events, and mental health status. Drawing on the findings of King et al. (1999), Marx et al. focused on those risk-resilience factors that were found to have the strongest relations with combat-related PTSD status. The entire sample was then divided into three equal subsamples, matched on PTSD diagnosis as well as on PTSD symptom severity. Two of these subsamples were used to derive and identify variables that significantly differentiated between individuals with and without PTSD. In order for a variable to be included in the instrument, the variable must

have significantly predicted PTSD diagnostic status, as well as attained a medium to large effect size in both derivation subsamples. A total of 12 variables met or exceeded the selection criterion. Marx et al. then derived empirically based cutoffs for each item that was not already dichotomous by using the risk difference statistic to determine which cutoff point best distinguished between those with and without PTSD. Because all 12 items met or exceeded the selection criterion in both derivation subsamples, subsequent analyses were conducted on the combined subsamples. The resulting instrument, the PTSD Statistical Prediction Instrument (PSPI), displayed strong internal consistency (Cronbach's $\alpha$ = .84), and excellent sensitivity (.90) and good specificity (.80).

Despite the exceptional success in developing methods to assess for PTSD, all of the current methods have inherent limitations. For example, both self-report scales and interview-based methods may be vulnerable to response bias (Frueh, Elhai, & Hamner, 2003). Further, reliance on a single assessment methodology or instrument may lead to an inaccurate diagnosis. As a result of these limitations, it has become standard practice to employ multiple methods and measures to better inform diagnostic decisions (see Keane, Wolfe, & Taylor, 1987). Such multimethod assessment of PTSD takes advantage of each measure's relative strengths, overcoming the psychometric limitations of any single instrument and maximizing correct diagnostic decisions.

### Treatment

Although PTSD is a relatively new psychiatric disorder, more than 50 randomized clinical trials (RCTs) examine treatments for the disorder. The treatment literature has been evaluated by conducting meta-analyses (e.g., Bisson & Andrew, 2006; Bradley, Greene, Russ, Dutra, & Westen, 2005), as well as by expert committees formed by the International Society for Traumatic Stress Studies (Foa, Keane, Friedman, & Cohen, 2009), Division 12 of the American Psychological Association (APA Presidential Task Force on Evidence-Based Practice, 2006) and the Institute of Medicine (Institute of Medicine, 2008). There is general consensus that cognitive-behavioral treatments, particularly treatments that include an exposure component, are effective in treating PTSD (see Keane & Kaloupek, 1982).

To date, no psychopharmacological treatment has been identified as effective in the treatment of PTSD. The U.S. Food and Drug Administration (FDA) approved the selective serotonin reuptake inhibitors sertraline and paroxetine for treating PTSD.

However, the approval was regulatory in nature and based on a risk–benefit analysis, which differs from the more rigorous standards used to define effective treatments for psychiatric disorders. Furthermore, approval by the FDA is generally not reconsidered except when new safety data emerges.

In terms of the cognitive-behavioral interventions, several evidence-based treatments for PTSD have been identified. These treatments include prolonged exposure (PE), cognitive processing therapy (CPT), and eye movement and desensitization reprocessing (EMDR).

Prolonged exposure involves the confrontation of the traumatic memory, as well as hierarchical in vivo (i.e., in person) exposure to objects, environments, and situations that remind the client of the trauma (Foa, Hembree, & Rothbaum, 2007). Exposure to the trauma memory occurs in session (i.e., imaginal exposure). These sessions are recorded, and the client is requested to listen to the recorded trauma account several times before the next session. In vivo exposures typically take place in between sessions as well. The purpose of the imaginal exposure is to allow the client to fully process the traumatic event, and to teach the patient that the traumatic memory is not inherently dangerous and is not the same as experiencing the trauma again. Confrontation of the trauma memory and in vivo exposures also allows the client the opportunity to experience her fear and anxiety without the need to escape or avoid. The treatment consists of up to twelve 90- to 120-minute sessions. Although a number of randomized controlled trials have demonstrated the efficacy of PE in the treatment of PTSD, the majority of these trials have examined female sexual assault survivors. Thus, there is some concern whether the observed efficacy of PE would be similar with other trauma samples, such as veterans with combat-related PTSD. In addition, PE tends to have a relatively high dropout rate (i.e., as much as 40%). One other concern is that the majority of randomized trials examining the efficacy of PE have been conducted by the same investigator or investigative team that developed the protocol, and this has led some to question the generalizability of the reported findings.

Cognitive processing therapy primarily focuses on challenging and changing distorted beliefs and self-blame regarding the traumatic event through Socratic questioning (Resick & Schnicke, 1992). An exposure component is also included in the protocol, such that clients are asked to provide a written account of the trauma event. Cognitive processing

therapy consists of twelve 60-minute weekly sessions. A recent study conducted by Resick and colleagues (2008) found that participants randomly assigned to a treatment condition that only included the cognitive restructuring component of CPT, and participants assigned to a treatment condition that only included the written account component of CPT benefited equally compared with participants randomly assigned to the full CPT protocol. However, participants who were assigned to the cognitive restructuring-only condition improved at a faster rate (i.e., within the first few weeks of treatment) than did participants who were assigned to the written account-only condition. This is an important finding, given the relatively large percentage of clients who drop out of PTSD treatment early in the course of treatment, and participants generally report greater distress to the exposure component of PTSD treatment (Foa, Zoellner, Feeny, Hembree, & Alvarez-Conrad, 2002). As with PE, the majority of the randomized trials of CPT have examined female sexual assault victims, although a recent study by Monson et al. (2006) found CPT to possess efficacy with male veterans diagnosed with chronic PTSD.

Eye movement and desensitization reprocessing pairs eye movements with cognitive processing of the traumatic memories (Shapiro, 1995). The initial phases of EMDR involve affect management techniques, such as relaxation. During the processing stage of therapy, the patient describes the traumatic memory and identifies and labels the images, beliefs, and physiological symptoms elicited by it. The patient is instructed to focus on these aspects of the traumatic memory while moving his or her eyes back and forth by tracking the therapists' finger (although other bilateral stimulation, such as finger-tapping, is used). The theoretical basis for EMDR is that PTSD symptoms result from insufficient processing/integration of sensory, cognitive, and affective elements of the traumatic memory. The bilateral eye movements are proposed to facilitate information processing and integration, allowing clients to fully process traumatic memories (Shapiro, 1995). There has been substantial controversy regarding the use of EMDR and the underlying mechanism of this treatment. There is some evidence that the mechanism of change is exposure, and that the eye movements are an unnecessary addition (Cahill, Carrigan, & Frueh, 1999; Davidson & Parker, 2001). Although some have concluded that there is sufficient evidence to recommend EMDR as an effective treatment for PTSD (e.g., APA Presidential Task Force on Evidence-Based Practice, 2006), others have concluded that

there is insufficient evidence to recommend it (e.g., Institute of Medicine, 2008).

Although we have made significant strides in our understanding of how best to treat those with PTSD, there are still some substantial gaps in our knowledge. Most trials exclude substance abuse, chronic pain, and traumatic brain injury. Given the high prevalence rate of these comorbid conditions in PTSD (e.g., Kessler et al., 1995), it is important to demonstrate whether these treatments are also effective in treating PTSD when these comorbid conditions are present.

An issue mentioned previously is that a large majority of RCTs focus on the treatment of female sexual assault survivors. Post-traumatic stress disorder resulting from other traumatic events, such as combat, may differ in terms of associated features (e.g., remorse related to committing acts of abusive violence, bereavement and loss, survivor guilt). Whether these types of issues are addressed in PE, CPT, and EMDR is an empirical question. As pointed out by the recent IOM committee report (2008), few RCTs have focused on veterans diagnosed with PTSD, one of the largest consumers of PTSD treatment. Another area in which the field needs to advance is conducting RCTs for group therapy for PTSD. Although group therapy is frequently used in clinical settings, there are currently no evidence-based group therapies for PTSD and the group RCTs that have been conducted are fraught with methodological shortcomings (Shea, McDevitt-Murphy, Ready, & Schnurr, 2009; Sloan, Feinstein, Beck, & Keane, 2009). Similarly, our knowledge of early interventions for PTSD is also very limited.

Another important area of investigation that has received limited attention to date is understanding how the evidence-based treatments for PTSD work (i.e., what are the mechanisms of action). Although the basic assumptions of some of these interventions are based upon the findings from basic research on learning and behavior in humans and nonhuman animals, mechanisms of action are rarely tested in RCTs. This is unfortunate, as understanding how or why a given therapy may work would help to identify the essential components of the treatment protocol, which could, in turn, facilitate the streamlining of treatment protocols and improve treatment outcomes.

## Conclusion

Work in the field of psychological trauma, PTSD, and dissociative processes is accelerating at unprecedented rates. Soon a sixth specialty journal will

join the field, just one indicator of the level of productivity in this clinical and research area. Articles on psychological trauma are now routinely published in the most prestigious journals in all of research, including *Science*, the *New England Journal of Medicine*, *Lancet*, the *Journal of the American Medical Association*, and *Nature*. This is an indication of the importance of the area in understanding human development, psychopathology, and health.

## Future Directions

Future studies in this area will be characterized by mixed models, methods, and measures (Keane, 2009) that will elevate the importance of the field. Investigators and clinicians are beginning to conduct integrative studies that examine risk and resiliency variables in the hope of understanding the key factors associated with the question of why some develop PTSD in the face of adversity while others do not. Studies that incorporate genetic methods, developmental strategies, physiological and psychophysiological measurement, and state-of-the-art assessment measures are gaining momentum in this field and are already beginning to influence the models and perspectives for understanding the development of PTSD and related conditions.

Studies are now ongoing in the developing as well as the developed world to establish that PTSD and dissociative constructs exist across races, cultures, languages, and other boundaries. This is dramatic progress and represents three decades of serious science, debate, and scholarly work. Although controversy may always surround the notion of psychological trauma, those of us involved in the scientific study of trauma exposure, PTSD, and dissociative reactions are gratified at the widespread acceptance of the importance of psychological trauma among the public, those in academia, governmental authorities, and policy makers (Gerrity, Keane, & Tuma 2001; Green et al., 2003).

# Eating Disorders

Robyn Sysko *and* G. Terence Wilson

### Abstract

*The Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV; American Psychiatric Association, 1994) describes two eating disorder diagnoses, anorexia nervosa (AN) and bulimia nervosa (BN). Provisional criteria are also provided in DSM-IV for binge eating disorder (BED), which is an example of an eating disorder not otherwise specified. This chapter presents a summary and synthesis of research related to the clinical features and treatment of AN, BN, and BED, including studies of prevalence, common comorbidities, and treatment efficacy. Both psychological and pharmacological treatments are reviewed, including cognitive-behavioral therapy, interpersonal psychotherapy, family therapy, and the use of antidepressant medications. Recommendations are made for future research across the eating disorders.

**Key Words:** Anorexia nervosa, bulimia nervosa, binge eating disorder, cognitive-behavioral therapy, antidepressant medication

This chapter presents a comprehensive overview of empirical research on eating disorders. General information is provided about the diagnostic criteria for eating disorders, prevalence and incidence of eating disorders, common comorbidities, treatment efficacy, and future directions for research in eating disorders. *The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition* (DSM-IV; American Psychiatric Association [APA], 1994) describes only two main eating disorder diagnoses, anorexia nervosa (AN) and bulimia nervosa (BN). However, provisional criteria for binge eating disorder (BED) are provided in the Appendix of DSM-IV, and as this diagnosis has generated a significant amount of attention and research since the publication of DSM-IV (Walsh, 2007), it will also be covered in the sections that follow.

## Anorexia Nervosa

Individuals meeting the diagnostic criteria for AN have a body weight below a minimally normal weight for age and height (e.g., less than 85% of expected); endorse a fear of weight gain or becoming fat; demonstrate a disturbance in body shape or weight, or the overvaluation of body shape and weight, or deny the seriousness of their current weight; and for postmenarchal females, experience amenorrhea for at least 3 months (APA, 1994). In the absence of regular binge eating and purging episodes, individuals are diagnosed with AN, restricting type (AN-R), whereas individuals with binge eating and purging behaviors (e.g., self-induced vomiting, laxative misuse) are classified as AN, binge-eating/purging type (AN-B/P; APA, 1994). This chapter summarizes information related to the presentation and treatment of AN, and suggests future directions for research on this disorder. Although the studies described in this chapter provide important information about the clinical course and outcome of patients with AN, a number of limitations are also evident, and are described in greater detail in upcoming sections. Additional research is needed

to better characterize the optimal treatment interventions for patients with AN.

Anorexia nervosa is a serious psychiatric disorder associated with significant morbidity and mortality (Sullivan, 1995; Steinhausen, 2002). Patients with AN are at risk for a range of medical complications, including cardiac abnormalities (e.g., bradycardia, hypotension, QT interval prolongation, QT dispersion, etc.), electrolyte abnormalities, osteopenia or osteoporosis, and endocrine disturbances (Mehler, Birmingham, Crow, & Jahraus, 2010). Long-term outcomes for individuals with AN are concerning, with less than half of the patients experiencing a full recovery, approximately one-third considered improved, and another 20% demonstrating a chronic course after a 4- to 10-year follow-up period (Steinhausen, 2002). Further, a recent study documented a six-fold increased mortality rate in comparison to the general population among individuals with AN, and 20 years or more after their first hospitalization, standardized mortality ratios for natural and unnatural causes were still high among patients with AN (Papadopoulous, Ekbom, Brandt, & Ekselius, 2009).

### Prevalence

Anorexia nervosa is a severe psychiatric disorder, but it is also a relatively rare condition. Hoek and van Hoeken (2003) reviewed epidemiologic studies of eating disorders, including AN, and found the average total number of cases in the population, or prevalence rate, was 0.29% (range of 0.0%–0.9%), with higher prevalence rates observed for subthreshold AN. A recent study examining AN among twins in Finland found an incidence, or number of new cases, of 270 per 100,000 person-years for individuals aged 15–19, and a lifetime prevalence of 2.2% for DSM-IV AN, and increased incidence and prevalence for broader definitions of AN (Keski-Rahkonen et al., 2007). Data documenting the incidence of AN among males are limited, but the female-to-male ratio of cases is estimated at 10:1 (Hoek & van Hoeken, 2003). The majority of studies related to epidemiology and treatment of AN focus on girls or women, and consequently much less is known about the clinical presentation of males with AN. Estimates of the incidence and prevalence of AN are further complicated by both the rarity of this disorder, which necessitates recruiting very large sample sizes, and patient characteristics, including secrecy and denial of patients, which interfere with the reporting of eating disorder symptoms (Grilo, 2006). Thus, it is not known whether these studies are accurately estimating the true prevalence and incidence rates for AN.

The prevalence of AN appears similar in Western and non-Western countries, suggesting that the effects of Western culture may be less prominent for AN than for other eating disorders (i.e., bulimia nervosa; Keel & Klump, 2003). Debate continues about whether the incidence of AN in the community has increased during the 20th century, or if other factors account for increases in the incidence of AN among youth, especially for 15- to 24-year-old females; however, larger numbers of identified cases have resulted in an increased need for treatment (Hoek & van Hoeken, 2003).

### Comorbidities

Patients with AN often describe symptoms consistent with other Axis I disorders. Clinical assessments of other psychiatric disorders are complicated by the presence of symptoms that may be secondary to low body weight or indicate an independent mood or anxiety disorder (e.g., depressed mood, low energy, obsessions, etc.). Patients with AN-R and AN-B/P report a prevalence of lifetime anxiety disorders of 33%–72% and 55%, respectively (Godart, Flament, Perdereau, & Jeammet, 2002). The prevalence of lifetime major depressive disorder ranges between 9.5% and 64.7% for patients with AN-R, and 50%–71% for patients with AN-B/P (Godart et al., 2007). Difficulties in differentiating Axis I mood or anxiety symptoms among patients with AN from the consequences of achieving a low body weight may explain some of the variability in these estimates. A substantial proportion of patients with AN also endorse a lifetime substance use disorder (Hudson, Hiripi, Pope, & Kessler, 2007), with a higher prevalence of alcohol or drug problems observed among individuals who binge eat (AN-B/P; Braun, Sunday, & Halmi, 1994; Bulik, Sullivan, & Slof, 2004; Herzog, Keller, Sacks, Yeh, & Lavori, 1992; Wiederman & Pryor, 1996). Recently, Root and colleagues (2010) observed higher rates of lifetime substance use disorders among a large sample of patients with a lifetime history of AN (n = 731) than did previous research (e.g., Braun et al., 1994; Herzog et al., 1992); however, patients with either alcohol or substance abuse or dependence were included in the analyses. With this broader definition of substance use, Root et al. (2010) also documented higher lifetime rates of alcohol and substance abuse and dependence among patients with binge eating or purging behaviors in comparison to those patients with a history of AN characterized by restricting without purging.

## Treatment Efficacy

Consistent with the low prevalence of AN, only a small number of controlled trials have evaluated treatments for this disorder, and the majority of these studies have focused on younger patients. Challenges in conducting research on patients with AN, such as the egosyntonic nature of the symptoms (Vitousek, Watson, & Wilson, 1998), high costs associated with more intensive treatment interventions (Agras et al., 2004), and significant medical complications that may necessitate withdrawing patients from treatment (Halmi et al., 2005), also slow the progress of research. Additionally, a number of different treatment options are needed for patients with AN (e.g., inpatient hospitalization, partial hospitalization/day treatment, outpatient treatment), and practitioners often use a combination of psychological and pharmacological interventions (Fairburn, 2005), which further complicates the process of conducting treatment research.

In general, research on psychological and pharmacological interventions for AN focuses on either acute treatment or the prevention of relapse to a low weight. Many of the trials described here have methodological flaws, including small sample sizes, short treatment durations or a small number of treatment sessions, limited follow-up, and others (Pike, 2009). Treatment trials for AN can be characterized by low rates of treatment acceptance (e.g., agreeing to participate in the trial), high rates of dropout, and questionable compliance with treatment (Halmi et al., 2005). Further, there is a notable risk that individuals with AN may need to be withdrawn from outpatient treatment studies to receive a higher level of care (Bulik, Berkman, Brownley, Sedway, & Lohr, 2007). However, despite these challenges, these patients are at risk for significant morbidity and mortality, and additional research to develop effective treatments is urgently needed.

## PSYCHOLOGICAL TREATMENTS

### Family Therapy

The greatest proportion of studies for the treatment of AN have examined the utility of family therapy. One particular form of family therapy, called the Maudsley form of family therapy (Lock, le Grange, Agras, & Dare, 2001), is the most commonly studied (Wilson, Grilo, & Vitousek, 2007). Initially, this approach involves the therapist training parents to function in a manner similar to that of inpatient staff, whereby the parents are entirely in control of their child's eating and weight (Lock et al., 2001). Subsequently, as the child gains weight, the second phase of the treatment allows the child greater autonomy and control, and the parents are less directly involved in refeeding (Lock et al., 2001).

The first investigation of Maudsley family therapy compared it to an eclectic supportive individual psychotherapy for preventing posthospitalization relapse among patients with AN (Russell, Szmukler, Dare, & Eisler, 1987). Russell and colleagues (1987) observed that, for younger patients with a shorter duration of illness, family therapy was superior to individual treatment; however, for patients older than 19 years of age with a longer duration of illness, the data suggested that individual treatment was more effective. In a 5-year follow-up of the Russell et al. (1987) report, Eisler and colleagues (1997) found evidence that these effects endured, as the benefits of family or individual therapy continued to be apparent for patients who were younger with a short duration of illness and older patients with a more chronic illness, respectively. Subsequent studies examining the Maudsley form of family therapy for adolescents with AN has focused on comparisons of varying types of the Maudsley approach (Wilson et al., 2007). Conclusions about the efficacy of family therapy for adolescents with AN are complicated by the possibility that patients under the age of 18 with a shorter duration of illness are more likely to respond, and by questions of whether family treatment is specifically beneficial or if other treatment interventions would show similar results (Fairburn, 2005).

### Cognitive-Behavioral Therapy

Cognitive-behavioral therapy (CBT) has been evaluated for the acute treatment of AN among outpatients in a small number of controlled trials. Garner and Vitousek first described a version of CBT for AN (Garner & Bemis, 1982, 1985; Garner, Vitousek, & Pike, 1997) that is similar to CBT as developed for BN (described later), but with a greater emphasis on issues related to low weight, weight gain (Garner et al., 1997), and increasing motivation for change and collaboration (Vitousek et al., 1998). The amount of time patients spend in treatment also differs substantially between CBT for AN and BN, with a recommendation of 1–2 years of treatment for patients with acute AN, and about 1 year for relapse prevention among individuals who enter treatment after weight restoration (Wilson et al., 2007).

Two studies utilizing CBT cannot be interpreted due to serious methodological issues, with the first noting a 100% dropout rate from the comparison treatment (nutritional counseling; Serfaty, Turkington, Heap, Ledsham, & Jolley, 1999), and

the second retaining less than 40% of patients across all groups (Halmi et al., 2005). A few studies have observed no differences in outcome for patients receiving CBT and other comparison therapies, including Channon and colleagues (1989), who examined the efficacy of three brief treatments, including CBT, a behavioral exposure treatment, and an eclectic control treatment. After 6 months of treatment, few significant differences were observed among the groups (Channon, DeSilva, Hemsley, & Perkins, 1989). Additionally, the authors noted that, although overall improvements were observed, the majority of patients were not weight restored and continued to experience eating-disordered symptoms (Channon et al., 1989). Ball and Mitchell (2004) compared CBT and behavioral family therapy for a younger sample of patients (ages 13–23), and in a completer analysis, observed no differences in weight or menstrual status between the treatment groups. For patients with broadly defined AN, McIntosh and colleagues (2005) compared CBT, interpersonal psychotherapy (IPT), and nonspecific supportive clinical management over 20 weeks. For the primary outcome measure of global AN rating, patients receiving nonspecific supportive clinical management demonstrated significantly better outcomes than the IPT group; however, other comparisons between treatments were not significantly different.

All three aforementioned studies included fewer treatment sessions than suggested by experts in CBT and utilized a form of CBT for AN that differed from what is recommended by the field (Wilson et al., 2007). Additional limitations include the small number of patients with AN (24–56), the inclusion of some individuals with a higher entry body mass index (McIntosh et al., 2005), and the fact that a significant proportion of patients did not complete a full course of therapy and/or did not demonstrate clinically significant improvements at the end of treatment.

Data supporting a specific effect of CBT are found in two studies focusing on the prevention of posthospitalization relapse among patients with AN. Pike and colleagues (2003) randomized patients to receive CBT or a nutritional counseling intervention over the year following discharge from an inpatient unit. At the end of treatment, significantly more patients in the nutritional counseling group met criteria for relapse (53%) in comparison to CBT (22%), and CBT was also superior when considering rates of premature dropout and percent of patients achieving a good outcome (Pike et al., 2003). More recently,

a nonrandomized study also found support for the superiority of CBT over community treatment as usual (Carter et al., 2009). Carter et al. (2009) observed that time to relapse, when defined as either a body mass index of 17.5 or less for 3 months or the resumption of regular binge eating and/or purging behaviors, was significantly longer for patients receiving CBT than for the treatment-as-usual group. Taken together, and in light of limitations similar to those described earlier, these studies suggest that nutritional counseling is not effective in preventing relapse among patients with AN and, although CBT has more promise for posthospitalization treatment, more data are needed.

## PHARMACOLOGICAL TREATMENTS

A number of small studies have evaluated the role of medications in facilitating weight restoration among patients with AN. For patients with acute AN, studies have examined antipsychotic medications such as chlorpromazine, pimozide, and sulpiride; antidepressants including clomipramine, amitriptyline, nortriptyline, and fluoxetine; and other medications including cisapride, an opiate antagonist (naltrexone), an antihypertensive (clonidine), hormones (testosterone, human growth hormone, estrogen/progestin), lithium, a serotonin antagonist (cyproheptadine), tetrahydrocannabinol, and zinc (Attia & Schroeder, 2005; Bulik et al., 2007; Crow, Mitchell, Roerig, & Steffen, 2009).

In general, the results of these studies were disappointing, with few suggesting any notable impact on weight gain; however, research evaluating pharmacological treatments for patients with AN typically utilize small sample sizes, are of short duration, and utilize medications primarily targeting appetite stimulation and comorbid symptoms of anxiety and depression (Attia & Schroeder, 2005; Crow et al., 2009). Additionally, the high percentage of patients with AN who will not accept a medication-only treatment, in combination with high dropout rates, has led some to argue that providing medication alone is not sufficient treatment for these individuals (Halmi et al., 2005). The failure to demonstrate a difference between active medication and placebo for either eating disordered or mood symptoms among patients with AN stands in contrast to studies of BN, which are described more fully later. However, newer agents may offer more promise for patients with AN. A recent study examined olanzapine, an atypical antipsychotic, versus placebo among 34 individuals attending a day treatment program in Canada (Bissada, Tasca, Barber, & Bradwejn, 2008).

Over the 13 weeks of the trial, all of the patients with AN gained weight, but patients randomized to olanzapine showed greater increases in body mass index, and a greater percentage achieved weight restoration in comparison to patients receiving placebo (Bissada et al., 2008). As the patients in the Bissada and colleagues (2008) study all participated in day treatment during the trial, additional studies are needed to evaluate the role of olanzapine without the addition of an intensive psychological intervention.

Two placebo-controlled studies have evaluated the utility of fluoxetine to prevent relapse following an inpatient hospitalization. In the first study (Kaye et al., 2001), some patients also received psychological treatment, which was not standardized, and in the second (Walsh et al., 2006), all patients received CBT in addition to fluoxetine or placebo. Kaye and colleagues (2001) found that fluoxetine-treated patients were more likely to complete the trial (63% completed) in comparison to patients receiving placebo (16% completed, $p$ = .0001), and patients who completed the trial tended to experience more weight gain and psychological improvement than patients who did not complete the trial. In the largest controlled medication trial for individuals with AN, Walsh and colleagues (2006) randomized 93 women to receive either fluoxetine or placebo. All of the patients were also provided with a CBT intervention, consisting of 50 individual treatment sessions. On almost all of the measures, the authors found little evidence for any significant benefit of fluoxetine compared to placebo (Walsh et al., 2006). In contrast to the Kaye et al. (2001) findings, Walsh et al. (2006) observed that fluoxetine did not affect time-to-relapse regardless of how dropouts from the study were classified, and the authors suggest that antidepressant medication is "unlikely to provide substantial benefit for most patients with anorexia nervosa" (p. 2611).

In summarizing the extant data on medication, Crow and colleagues (2009) state "at present, there is no convincing evidence of efficacy for any drug treatment for AN in either the acute or chronic phase of the illness" (p. 1). Crow et al. (2009) suggest a number of possible explanations for the lack of efficacy of psychopharmacological treatments for AN, including: medication compliance, complications from the impact of starvation (e.g., nutritional deficits, problems with cognitive function), use of medication monotherapy, the choices of outcome measures and treatment targets, few animal models of AN, limited attention from pharmaceutical companies, and the possibility that AN is not responsive to medication treatment. To address these limitations, Crow and colleagues (2009) propose solutions such as considering alternative targets for medications (e.g., fear conditioning), utilizing different measures (e.g., laboratory measures of feeding behavior), conducting shorter pilot trials of medication, identifying new strategies for drug development, focusing on the symptoms that most affect functioning and outcome among patients with AN, and modifying the existing clinical trials system to increase recruitment. The studies of pharmacological treatments to date have not been promising, but options do exist for continuing to examine medication options for patients with AN.

*Early Response*

Body weight, body composition, and nutritional status appear to be important in the prevention of relapse among patients with AN. A few recent studies have highlighted the specific importance of early changes in these domains in predicting individuals with AN who will subsequently relapse or maintain a normal weight after inpatient hospitalization. Schebendach and colleagues (2008) examined dietary choices and the food intake of inpatients after reaching 90% ideal body weight in predicting outcome, as measured by the Morgan-Russell criteria (Morgan & Russell, 1975), following discharge from the hospital. Although there were no differences in total calorie intake between the successful and unsuccessful groups, individuals classified as treatment failures as outpatients were found to report a lower total fat intake and measures of diet energy density and diet variety (Schebendach et al., 2008). The authors suggested that patients with AN who consume a large proportion of their calories from low-energy-density foods (e.g., fruits, vegetables), and eat a limited range of foods as inpatients may have difficulty maintaining a diet with sufficient calories (Schebendach et al., 2008). In addition, body composition, and specifically percent body fat, measured after acute inpatient weight restoration has also been identified as a significant predictor of later outcome by Morgan-Russell criteria (Mayer et al., 2007). The Mayer et al. (2007) study found no differences in body mass index ($kg/m^2$) between groups of patients with AN considered to be "treatment successes" or "treatment failures" after discharge from the hospital, but body fat, as measured by dual-energy x-ray absorptiometry, differed between the two groups. Thus, this study suggests that the failure to restore patients with AN to a level of body fat similar to that of healthy women during an inpatient hospitalization

may increase the risk for relapse. Finally, a secondary analysis of the data from the Walsh, Kaplan, and colleagues (2006) study of fluoxetine and CBT found that patients with a higher body mass index and a lower rate of weight loss in the first month after hospitalization predicted successful weight maintenance after 6 months (Kaplan et al., 2009). Taken together, these studies suggest that, to increase the likelihood of success after inpatient treatment, prior to leaving the hospital, patients with AN should have a normal percentage of body fat and a higher body mass index and a diet that includes both a range of foods and calorie-dense foods. Further, body weight in the first month following inpatient treatment should be carefully monitored, as more intensive treatment interventions may be required for patients with AN who are rapidly losing weight.

### Future Directions

Additional research on AN is a priority due to both the notable morbidity associated with this disorder and the limited extant data (Agras et al., 2004). However, the rarity of AN and the challenges associated with enrolling patients in treatment trials makes progress very difficult. Many patients with AN are hospitalized to manage the serious medical risk associated with this disorder; however, no controlled studies suggest how to determine the appropriate level of care. The use of a stepped-care approach is one possibility (Agras et al., 2004). In addition, at this time, studies of pharmacological treatments have not identified substantial benefit for patients with AN, but there are emerging agents that offer possibilities for future research. Identifying effective psychotherapies for patients with AN will likely be challenging (Wilson, 2010a), and the development of individual treatments, given the extant data on family therapy, should be a priority (Wilson et al., 2007).

### Bulimia Nervosa

Patients with DSM-IV BN experience episodes of binge eating and inappropriate compensatory behavior on average twice per week over a 3-month period (APA, 1994). The DSM-IV definition specifies that binge eating episodes consist of eating in a distinct period of time an amount of food that is larger than others would eat in similar circumstances, along with a sense of loss of control over eating. This chapter summarizes information related to the presentation and treatment of BN, and suggests future directions for research on this disorder. In contrast to the literature described earlier for patients with AN, more consistent and positive results are identified in treatment studies of BN; however, challenges, such as dissemination and implementation of empirically based approaches, remain.

Individuals with BN are also at risk for medical complications from their eating disorder, such as dental erosion, swollen salivary glands, esophageal tearing, and electrolyte abnormalities (Mehler et al., 2010). Consequently, a medical assessment by a clinician familiar with the potential medical complications resulting from BN is recommended for patients at the beginning of treatment (Mehler et al., 2010). The measurement of clinical outcome among patients with BN is complicated by the lack of standardized definitions for remission, recovery, or relapse from this disorder (Shapiro et al., 2007). However, using available data, Steinhausen and Weber (2009) observed mean recovery rates of 45%, mean improvement rates of 27%, and mean chronicity rates of 23% for patients with BN among 27 studies classifying outcome using these three categories. These rates for recovery, improvement, and chronicity are similar to a prior review by Steinhausen (2002) examining studies of AN; however, the mean crude mortality rate for individuals with BN (0.32%; Steinhausen & Weber, 2009) was lower than that observed for AN (5%; Steinhausen, 2002).

### Prevalence

Extant data on the prevalence and incidence of BN in the population suggest that this disorder is more common than AN, but still relatively rare. The aforementioned review by Hoek and van Hoeken (2003) found an aggregated prevalence rate for BN of 1.0%, with a range of 0.0%–4.5% from 12 studies identified in the literature since 1990 and, similar to AN, higher prevalence rates are observed for subthreshold cases of BN. A longitudinal study of twins in Finland identified a similar lifetime prevalence of DSM-IV BN (1.7%), with a small proportion (21%) classified with nonpurging BN (Keski-Rahkonen et al., 2009). Similar to the trends previously described for AN, few studies examine the prevalence of BN among males. The available data suggest an estimate for the lifetime prevalence of 15- to 65-year-old men of 0.1% (Hoek & van Hoeken, 2003). Although the identification of AN in the population is complicated by the rarity of the disorder, research on the incidence of BN is influenced by the fact that earlier versions of the DSM and International Classification of Diseases (ICD-9; World Health Organization, 1978) did not provide a specific diagnostic code for this disorder (Hoek & van Hoeken, 2003).

### Comorbidities

Many treatment-seeking individuals with BN are also diagnosed with co-occurring psychiatric disorder, including mood and anxiety disorders. Approximately 20%–80% of patients with BN are classified with a lifetime major depressive disorder, and lifetime prevalence rates for anxiety disorders are between 41% and 75% (Godart et al., 2007; Godart et al., 2002). In treatment trials for BN, a significant proportion of patients have a diagnosis of major depressive disorder, but treatment with CBT or medication typically results in significant improvements in these comorbid symptoms of depression (Walsh, Fairburn, Mickley, Sysko, & Parides, 2004; Wilson & Fairburn, 2002). Estimates of the co-occurrence of BN and substance use disorders are also greater than chance, with between 3% and 50% of patients with eating disorders estimated to have a comorbid diagnosis of substance abuse or dependence (Bulik, Sullivan, & Slof, 2004), with a median prevalence of 22.9% (Holderness, Brooks-Gunn, & Warren, 1994).

### Treatment Efficacy

#### PSYCHOLOGICAL TREATMENTS

##### Cognitive-Behavioral Therapy

The model underlying CBT for BN emphasizes the critical role of both cognitive and behavioral factors in maintaining bulimic symptoms. The overvaluation of an idealized body weight and shape is of critical importance and leads to rigid dietary restriction. Dietary restriction subsequently produces a vulnerability to periodic binge eating episodes, which are characterized by a loss of control over eating. Attempts to counteract the effects of binge eating, such as self-induced vomiting and other extreme weight control behaviors, also maintain binge eating by reducing anxiety about weight gain and disrupting the development of satiety. Binge eating and purging cause distress and low self-esteem, which reinforce circumstances that will lead to continued dietary restraint and binge eating (Fairburn, 1997a; Fairburn, Cooper, & Shafran, 2003). Cognitive-behavioral therapy assists in the development of a regular pattern of eating and problem-solving skills for coping with high-risk situations, modifying problematic shape and weight concerns, and preventing relapse (Fairburn, Marcus, & Wilson, 1993).

Extant data on the efficacy of CBT for patients with BN, including typical remission rates for binge eating and purging of 30%–50% (Wilson et al., 2007), led the National Institute for Health and Clinical Excellence (NICE, 2004) to designate this type of treatment as the treatment of choice for adults. Further, CBT has been shown to be superior to other psychological treatments in the short-term (Wilson & Fairburn, 2007) and antidepressant medications for achieving abstinence from bulimic symptoms (Wilson et al., 2007). The effects of manual-based CBT for BN are seen not only for improvements in binge eating and purging, but also for other psychiatric comorbidities (e.g., depression), self-esteem, and social functioning (Wilson, 2010a). Although CBT is a robust treatment with long-lasting effects, improvements are still needed, as a significant portion of patients remain symptomatic after receiving 16–20 sessions of treatment.

Fairburn (2008) has developed an enhanced version of CBT (CBT-E) that promises to be the most effective treatment available. CBT-E is "trans-diagnostic" in that it focuses on the commonalities among the eating disorders rather than exclusively directing treatment toward DSM-IV eating disorders. Consistent with this focus, CBT-E provides for a highly individualized form of treatment that emphasizes personalized treatment formulations. The core treatment consists mainly of the earlier Fairburn et al. (1993) manual, with two major changes. The first is a reformulated strategy and method for addressing dysfunctional body weight and shape concerns, and the second is the addition of an explicit treatment module for what is called "mood intolerance" as a specific trigger of binge eating and purging. The primary focus on eating disorder symptoms is supplemented by the flexible use of additional treatment modules designed to address common maintaining mechanisms, namely, core low self-esteem, clinical perfectionism, and interpersonal functioning. The first controlled evaluation of CBT-E for BN indicated that it appears to be a more effective treatment for complex cases of BN (Fairburn et al., 2009).

##### Interpersonal Psychotherapy

Interpersonal psychotherapy (IPT) was adapted for BN by Fairburn (1997b) from the short-term treatment for depression developed by Klerman, Weissman, Rounsaville, and Chevron (1984). In contrast to CBT for BN, IPT for BN does not directly focus on the modification of binge eating, purging, other disturbed eating, or overconcern with body shape and weight. Instead, IPT for BN focuses exclusively on interpersonal issues and construes eating disturbances as a way to understand the interpersonal context, which is assumed to be maintaining bulimic symptoms. Two large randomized-controlled studies of patients with BN found IPT to be significantly

less effective than CBT at the end of treatment (Agras, Walsh, Fairburn, Wilson, & Kraemer, 2000; Fairburn, Jones, et al., 1993). Differences between the two treatments were no longer statistically significant at the 1-year follow-up. As these studies did not include any form of a control treatment, the improvement associated with IPT cannot be associated with a specific treatment effect. However, in a study by Fairburn et al. (1995), both IPT and CBT demonstrated significant improvements over a comparison treatment (a form of behavior therapy without the cognitive features of CBT) for individuals with BN over the course of follow-up. This single study provides specific evidence of the efficacy of IPT for BN.

*Family Therapy*

Two studies have evaluated the Maudsley form of family therapy for adolescents with BN. In the first, Le Grange and colleagues (2007) examined family therapy and supportive psychotherapy, and found equivalent improvements from pre- to post-treatment for most eating disorder symptoms, self-esteem, and depressive symptoms. However, in comparison to supportive psychotherapy, family therapy produced significantly higher rates of remission from eating disorder symptoms post-treatment. The second study, by Schmidt and colleagues (2007), compared family therapy to a cognitive-behavioral self-care treatment, and found a significantly larger proportion of adolescents receiving cognitive-behavioral self-help to be abstinent from binge eating at the end of treatment. The two treatments were similarly efficacious with regard to abstinence from self-induced vomiting (Schmidt et al., 2007). On the basis of these studies, it appears that family therapy is useful for younger patients with BN, but the Schmidt et al. (2007) results suggest that this type of treatment may not be more effective than other treatments, such as a self-help form of CBT, which is discussed next.

*Guided Self-Help*

Despite the effectiveness of CBT in the treatment of BN, access to this type of treatment in the United States is limited. Variables affecting the availability of CBT include the amount of time needed to administer CBT (20 50-minute sessions over 4–5 months); challenges related to training and supervising therapists to administer CBT; and the small number of available CBT therapists (Sysko & Walsh, 2007). Self-help programs using the principles and procedures of CBT were developed to help overcome these barriers. Guided self-help (CBTgsh) combines a self-help manual with a limited number (e.g., 8–10) of brief therapy sessions (Fairburn, 1995) with therapists who may vary widely in terms of experience and expertise (Fairburn, 1995).

Several studies have shown that CBTgsh is effective with at least a subset of patients with BN (Wilson, 2010a). For example, Banasiak et al. (2005) found that primary care physicians trained and supervised in CBTgsh obtained significantly superior results as compared with a delayed treatment control condition. The results were maintained at a 6-month follow-up, and rivaled the outcomes of more standard manual-based CBT. The aforementioned study by Schmidt and colleagues (2007) compared family therapy (based on the Maudsley model) with CBTgsh, consisting of ten weekly sessions, three monthly follow-up sessions, and two optional sessions with a "close other." Both treatments resulted in significant improvement in binge eating and purging at the end of treatment (6 months) and a follow-up at 12 months, but CBTgsh resulted in significantly more rapid reduction in binge eating. Moreover, CBTgsh was associated with greater acceptability and a lower cost than family therapy. Questions still remain regarding the level of training, degree of supervision, and type of setting that is needed for the effective implementation of CBTgsh (Sysko & Walsh, 2007). Widely varying results have been reported across different studies, and inexperienced and unsupervised healthcare providers with minimal training in CBTgsh are ineffective. Nevertheless, even though the successful use of CBTgsh requires specific therapist selection, training, and supervision, it still provides a briefer, less costly, and more readily disseminable intervention to a wider range of health-care providers than does formal, manual-based CBT.

PHARMACOLOGICAL TREATMENTS

A recent systematic review of medication studies for the treatment of BN identified 12 trials that were given a quality rating of "good" (Shapiro et al., 2007). Half of the trials in the Shapiro et al. (2007) review compared fluoxetine and placebo, which is currently the only medication approved by the U.S. Food and Drug Administration (FDA) for the treatment of BN. Most of these studies found significant decreases in binge eating and purging resulted from the administration of 60 mg of fluoxetine. Other positive medication trials included the antidepressants fluvoxamine, desipramine, trazodone, and brofaromine; the anticonvulsant topiramate; and a $5HT_3$ antagonist (ondansetron; Shapiro et al., 2007). Although some effective medication treatments have

been identified, there are a number of limitations to the existing literature. For example, there are few studies examining selective serotonin reuptake inhibitors other than fluoxetine, few data on the use of antidepressants for adolescents with BN, and the optimal duration of treatment with medications is not known (Broft, Berner, & Walsh, 2010).

*Early Response*

The time course of response to CBT and antidepressant medications has been examined for patients with BN. Wilson et al. (1999) analyzed the time to treatment response in a study in which patients were randomly assigned to one of five treatment groups (Walsh et al., 1997). Four of the groups received a combination of psychotherapy (CBT or supportive psychotherapy) and antidepressant medication or placebo under double-blind conditions. A survival analysis was used to identify the time to improvement among the four treatment conditions (CBT + medication, CBT + placebo, supportive psychotherapy + medication, supportive psychotherapy + placebo), with response defined as a 75% reduction in binge eating or vomiting from baseline for a minimum of 2 weeks. A significant main effect was observed for CBT in comparison to supportive psychotherapy, indicating that CBT produced significantly more rapid reductions in binge eating and vomiting than did supportive psychotherapy. Sixty-one percent of patients receiving CBT across medication conditions were early responders for binge eating, and 61% were early responders for vomiting, in comparison to 27% for binge eating and 30% for vomiting among patients receiving supportive psychotherapy across medication conditions. These data suggested that the response to CBT in BN begins in the first few weeks after beginning treatment.

A second study by Wilson and colleagues (2002) examined the time to response in a study of women with BN randomized to receive either CBT or interpersonal psychotherapy (IPT; Agras et al., 2000). Similar to the findings of Wilson et al. (1999), rapid improvements were observed among patients receiving CBT, with 62% of the post-treatment improvement evident by the sixth week of treatment. The pattern of early response observed by Wilson et al. (2002) was further explored by Fairburn and colleagues (2004). Using a classification tree analysis, Fairburn et al. (2004) examined predictors of response at the end of acute treatment and outcome 8 months after the end of treatment and found that early change in the frequency of purging (after 4 weeks) in both types of treatment was a significant predictor of post-treatment response. Surprisingly, early change in purging was also a predictor of outcome 8 months after the termination of treatment. Response to psychological treatments for BN begins in the first few weeks, and early response is predictive of longer-term outcome.

Similar findings are also observed when examining antidepressant response among patients with BN, including one study that suggested that individuals who do not respond to antidepressant medication can be reliably identified early in treatment (Walsh, Sysko, & Parides, 2006). Specifically, 80%–85% of patients would be correctly identified as eventual nonresponders to desipramine by the second week of treatment. However, this study had several notable limitations, including the relatively small sample of patients with BN ($n = 77$) and the now infrequent use of desipramine to treat BN. In a more recent study of the antidepressant fluoxetine (Sysko, Sha, Wang, Duan, & Walsh, 2010), a majority of patients with BN who do not respond could be identified early in treatment, specifically by the third week. At week 3, if fluoxetine was discontinued for patients with less than a 60% reduction in binge eating, approximately 73% would be correctly classified as eventual non-responders to fluoxetine and 23% of patients who would eventually respond to fluoxetine would be misclassified as non-responders. For patients with less than a 60% decrease in vomiting at week three, approximately 72% would be correctly classified as non-responders and 22% would be misclassified.

### Future Directions

Although effective treatments are available for patients with BN, additional research is needed to assist those patients who fail to respond to the existing empirically supported treatments. Wilson and colleagues (2007) suggest that treatment efficacy for patients with BN could potentially be improved in a number of ways, including identifying robust moderators of outcome; combining or sequencing antidepressant medications with CBT; combining or sequencing CBT with other theoretically compatible treatments, such as dialectical behavior therapy; and enhancing existing manual-based CBT. Further, Wilson (2010b) suggests focusing on variables that have been identified as clinically useful predictors of outcome in studies of BN, including negative affect and early response. Although it is important to improve existing treatments for BN, the most significant research questions relate to how best to disseminate these

treatments to individuals for whom access to specialty care is limited.

Training in empirically supported treatments is scarce, and there is limited information about how to provide training, supervision, and ensure the fidelity of these treatments (Wilson, 2010b). Further, empirically supported treatments should be simplified to allow their use by a wider range of mental health professionals, such as by employing self-help versions of these interventions (Wilson, 2010b).

## Eating Disorder Not Otherwise Specified

Eating disorder not otherwise specified (EDNOS) is a heterogeneous and poorly specified diagnostic category in DSM-IV that consists mainly of variations of AN, BN, or mixed disorders containing features of both AN and BN. As discussed here, the exception is BED, for which provisional diagnostic were published (APA, 1994). EDNOS is the most common eating disorder diagnosis health-care professionals encounter in routine clinical practice. Disorders within this category are as clinically severe as AN and BN (Fairburn, Cooper, et al., 2007). For example, a longitudinal assessment of mortality in a large sample of individuals with eating disorders found that those with EDNOS had elevated mortality risks, similar to those seen in AN (Crow, Peterson, et al., 2009). Moreover, the same study revealed an increased risk of suicide across the different eating disorder diagnoses.

Fairburn and colleagues (2009) reported the only treatment study enrolling a wide range of normal-weight individuals with an EDNOS. The treatment provided in this study was CBT-E, as summarized in the previous section on BN, and as CBT-E is based on a transdiagnostic model that assumes that all eating disorders have common underlying mechanisms, CBT-E seems well-suited to treating EDNOS. Fairburn (2008) describes two main versions of CBT-E for the full range of eating disorder patients, namely, a "focused" (CBT-Ef) and a "broad" treatment (CBT-Eb). The former is very similar to the Fairburn et al. (1993) manual as described earlier, with the two main changes consisting of a reformulated strategy and method for addressing dysfunctional body weight and shape concerns, the addition of an explicit treatment module for what is called "mood intolerance" as a specific trigger of binge eating and purging. CBT-Eb is based on a broader model of the processes that are hypothesized to maintain BN, and incorporates an expanded range of strategies for treating these additional maintaining mechanisms.
